NEW YORK, SATURDAY, NOVEMBER 21, 1885.

PASTEUR'S PREVENTIVE INOCULATION OF HYDROPHOBIA.

In another part of this issue we reproduce from the "Medical Times and Gazette," of London, a brief but very satisfactory account of M. Pasteur's system of protective inoculation of rabies. Under any circumstances, the results which M. Pasteur has been enabled to report to the *Académie de médecine* could not fail to prove of surpassing interest, but just at the present time they seem to come most opportunely, for hydrophobia is so prevalent in England as to be termed epidemic, and many cases have lately been reported in Paris.

It would be premature to settle down to the conviction, on the strength of Joseph Meister's case, that an infallible preventive had at last been found of a disease which, although, fortunately, of comparatively rare occurrence, is undoubtedly the most horrible in all our nosology, whether we regard the torturing uncertainties of its variable and often extremely protracted period of incubation, the uniformity with which it destroys life, or the terrible suffering that attends its course. But, while we would not hastily accept this comforting conclusion, on the other hand we have little patience with the pertinacious objectors who seem bent on belittling every step in Pasteur's course of investigation, and ready to attribute Meister's escape thus far to anything but the inoculations. Almost every innovation in medicine has to encounter a hand-to-hand resistance. Tantalizing as the process is, it is not wholly a disadvantage, for it guards against our falling lazily into a blind acceptance of what happens to be at the same time plausible and agreeable. In our estimate of such a matter as the Pasteur system of inoculation, we should divest ourselves alike of credulous enthusiasm and of over-skepticism.

The main considerations to be taken into account are, briefly, these: The dog that bit young Meister was not absolutely proved to have been mad. As is too often the case, it was killed before the clinical features had declared themselves unmistakably. Nevertheless, so long as it was permitted to live it showed the symptoms common to dogs in the early stage of the disease, and at the post-mortem its stomach was found stuffed with the refuse that competent observers have declared to be a conclusive sign of the depraved appetite characteristic of hydrophobia. The boy was terribly bitten, not in one place, but in many, and in portions of the body where the probability of inoculation is at its highest. The cauterization was not done until twelve hours after the bites had been inflicted; it was then done, not with a hot iron, but with carbolic acid, and we are told that some of the wounds were not cauterized at all. But, even if we admit that the cauterization protected the boy against hydrophobia as the result of the bites, we can not for a moment entertain the idea that it also rendered him proof against the fatal result that would, almost to a dead certainty, have followed M. Pasteur's inoculation of the intensified virus, except for the protective effect of the preparatory inoculations. Even the theoretical objection that the rabies of rabbits is not communicable to other than herbivorous animals fails to break the force of this last statement, for Pasteur himself has shown that it can be communicated to the *Carnivora*. Unless, as the "Gazette hebdomadaire de médecine et de chirurgie" suggests, we are content to rest our last doubt on the insufficient time that has elapsed since Meister was bitten, we must conclude, then, either that he has been saved from hydrophobia by M. Pasteur, or that he was born into the world with a most remarkable immunity. It is true that the period of incubation is sometimes very long, and that but little more than three months have elapsed since Meister was last inoculated; but in most cases the disease declares itself within that length of time, especially in the young. In view of all these considerations, we must admit that the probabilities are gratifyingly in favor of the belief that M. Pasteur has at last succeeded in furnishing us with a means of preventing this terrible disease, but, of course, time alone can confirm or overturn our expectations.

THE PROPOSED REGULATION OF MEDICAL PRACTICE IN THE STATE OF NEW YORK.

The president of the New York State Medical Association, in his address delivered before that body last Tuesday, took decided ground against State legislation intended to affect medical education. It is well known that for two or three years past the Medical Society of the State of New York—and our distant readers should bear in mind the distinction between the two societies—has been trying to obtain such legislation as would make the right to practice depend upon a State license. The prevailing idea has been that this license should be granted only after a State examination, regardless of candidates' diplomas. Legislation of this sort would, of course, have an effect upon the teaching in the medical colleges of the State, but the effect would be an indirect one, bearing scarcely more upon the New York colleges than upon others, and that it would be wholesome there can be no doubt. It certainly need not involve any interference with the curriculum of a college or with its methods of teaching.

There is no lack of honest and capable men who are opposed to such legislation, or at least distrustful of it, and it must be confessed that the questions involved in the project are by no means easy of solution, but it is somewhat disheartening to find such an issue raised in connection with it as one of those which were raised in the address alluded to—both because we think the issue irrelevant and because we think that the implied appeal to the material interests of the New York colleges is one that they themselves would scarcely feel comfortable in urging upon the attention of the Legislature.

Dr. Gray expressed his apprehension that the legislation proposed would "transfer students who came to the medical colleges of New York from all parts of the country, and from

foreign countries, to the schools of Boston, Philadelphia, and other cities." We have before heard this fear expressed in private, but never before, so far as we are aware, has it been put forward in public. We do not believe that the profession of the State would attach much weight to an argument of this sort, even if it were well founded, which it certainly is not, in our opinion; for it plainly puts self-interest above all other motives, and it is in no such temper that the Medical Society of the State of New York has taken up the question. We can not, indeed, think that the colleges are willing to put themselves publicly in the position of trying to obstruct legislation in the interest of progress simply because they think they may lose a few students.

Unless Dr. Gray's understanding of the proposed legislation differs radically from ours, he can only have had in mind the regulation of the right to practice by the State, and not any interference with the college requirements for graduation. As we view the matter, there is not the slightest danger that such legislation will work the least injury to the colleges. The question will be as to the means of obtaining a license to practice in this State, and the graduate of a New York college will not be at any disadvantage. Students who intend to practice in this State will not be enabled to slip through any more easily by having taken their college courses or their diplomas elsewhere, and those who intend to practice in some other State will in no wise be affected by the New York law. We do not believe, therefore, that the legislation in question will lead a single student away from New York.

MINOR PARAGRAPHS.

THE NEW YORK STATE MEDICAL ASSOCIATION.

As we go to press, the second annual meeting of the association is in progress at the Murray Hill Hotel, and we give a portion of the proceedings in this issue of the Journal. The necessity of holding evening sessions testifies to the amount of work that is being done, and, judging from the reports of the proceedings thus far received at this office, we feel safe in saying that the quality of the papers read is in general quite up to what was expected of this new and energetic body. A particularly commendable feature of the programme is the grouping of papers dealing with the same subject from different points of view. The attendance is large and representative of the various sections of the State, and the meeting must be said to be decidedly successful.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 17, 1885:

DISEASES.	Week ending Nov. 10.		Week ending Nov. 17.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	3	0
Typhoid fever	23	6	25	8
Scarlet fever	20	5	21	0
Cerebro-spinal meningitis	1	1	4	4
Measles	5	1	13	4
Diphtheria	56	25	59	28
Small-pox	8	2	7	2

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, November 11th: *Montreal, Canada.*—For the week ending November 11th: 143 deaths from small-pox in the city, and 93 in adjoining municipalities as compared with 233 and 89, respectively, during the week ending November 4th. Reports received at this office indicate that the number of deaths occurring in the city from the disease is steadily declining, while the area of the infected district beyond the city limits is as steadily increasing. Twenty-nine places were reported infected November 7th. The City Auditor of Montreal reports, under date of November 5th, an expenditure of $40,799.79 in connection with the epidemic, and states that he believes the total expense to that date will reach $100,000. *Kingston, Canada*, November 13th: Free from small-pox. *Toronto, Canada*, November 7th: Free from small-pox. *Matanzas, Cuba*, November 4th: Free from epidemic diseases. *Nassau, N. P.*, October 24th: Free from epidemic diseases. *Acapulco, Mexico*, October 25th: Health of city improving. *Guaymas, Mexico.*—For the month of October: 6 deaths from yellow fever. No cases of fever have been reported at other towns in the consular district. *Buenos Ayres.*—For the month of May: 92 deaths from small-pox. *London, England.*—For the week ending October 31st: 9 deaths from small-pox. Cases in hospital, 88; admissions during the week 14, as against 11 in the preceding week. *Paris, France.*—For the week ending October 31st: 8 deaths from small-pox. *Bordeaux, France.*—From October 17th to 31st: 5 deaths from small-pox. *Antwerp, Belgium.*—From October 17th to 31st: 3 cases and 2 deaths from small-pox. *Copenhagen, Denmark.*—For the month of September: 45 deaths from small-pox. *Zurich, Switzerland.*—For the week ending October 21st: 2 deaths from small-pox. *Prague, Bohemia.*—For the week ending October 29th: 7 deaths from small-pox. *Trieste, Austria.*—From October 10th to 24th: 15 cases and 4 deaths from small-pox. *Barcelona, Spain.*—From October 10th to 20th: 169 cases and 78 deaths from cholera. October 18th to 20th, no new cases or deaths reported. *Cadiz, Spain.*—For the week ending October 31st: Cholera has disappeared, and clean bills of health are to be issued after November 1st. *Gibraltar, Spain.*—For the week ending October 25th: No new cases of cholera since October 13th. Sporadic cases still reported in neighboring Spanish villages. Dengue prevalent. *Genoa, Italy.*—From October 18th to November 1st: 20 cases and 1 death from small-pox. *Leghorn, Italy.*—For the week ending October 25th: 1 death from small-pox. *Venice, Italy.*—From October 3d to 17th: 16 cases of small-pox. *St. Petersburg, Russia.*—For the week ending October 24th: 1 death from small-pox. *Warsaw, Russia.*—From October 3d to 17th: 3 deaths from small-pox. *Calcutta, India.*—From September 19th to October 3d: 13 deaths from cholera and 1 from small-pox. *Hioga, Japan.*—For the week ending October 10th: 22 cases and 21 deaths from cholera.

Scarlet Fever in Boston.—It is reported that the disease is increasing in certain portions of the city.

The Sanitary Inspection on the Canadian Frontier.—Under date of November 10th, Surgeon H. W. Austin, of the Marine-Hospital Service, reports to Surgeon-General Hamilton as follows:

"I have the honor to report that I completed the inspection of all Vermont stations November 6th, and then returned to Burlington, Vt. Awaiting my return was a large amount of mail requiring immediate attention, and, having no clerk, it consumed considerable time to dispose of it; hence the delay in re-

porting the result of my inspection. Considerable complaint was beard that only a part of Montreal baggage was disinfected at our stations, and that it must be done at the points of destination. To satisfy local and State health officers, and in order that every possible precaution might be taken, I issued an order to all Vermont inspectors, and to the inspectors on duty at Rouse's Point, to thoroughly disinfect all Montreal baggage, and this is now being carried out. Each station has a well-equipped fumigation building, where the baggage is opened and hung up on hooks, and allowed to remain in sulphurous-acid gas for four to twelve hours, according to the nature of the articles to be disinfected. Three pounds of sulphur are burned in one thousand cubic feet of space. The baggage is then carefully put back into the trunks, which are then checked and sent on to their destination. Very few certificates of vaccination are at present accepted by our inspectors, but the arm is examined instead, and all are vaccinated when considered necessary. Large quantities of freight, consisting of household goods, are disinfected at each station. This is generally done in a freight-car which is suitable for the purpose. To illustrate the faithfulness or thoroughness with which the work is done aboard the trains, and the various ways resorted to by certain emigrants, I will cite a few incidents. At Ogdensburg, N. Y., an Indian of some Canadian tribe was met on the ferry by our inspector, and he was asked the question whether he had been vaccinated. He replied, 'Indian had not been vaccinated and not propose to be.' He was informed that he would have to return unless he allowed the inspector to vaccinate him. He reluctantly consented, and when the vessel arrived at port it was found that he had baggage that required disinfection. To this he strongly objected, but, rather than have it returned, gave it over to the inspector, who put it in the fumigation building. He waited and watched the process with great interest, and, as soon as the door was opened, plunged into the room where the smoke was so dense that nothing could be seen, but returned in a second (well fumigated), but nearly suffocated. He finally received his baggage and started. He immediately got drunk, was put in the lock-up by the city authorities, and was returned to Canada the next morning, he being without means of support.

"On one of the trains a woman slipped by the inspector and entered the water-closet. She was allowed to remain there two hours, and then a brakeman rapped for her to come out. She refused to do so, and had to be taken out by force. She was vaccinated and allowed to pass. Passengers will mutilate their own arms and produce the wound as evidence of vaccination. They have been detected in doing this, but it does not often succeed. They frequently wipe off the virus after they have been vaccinated, and always, when they are discovered, must submit to revaccination. It will be seen that over certain railroads twenty per cent. of all passengers are vaccinated. The fumigation of baggage is performed by the baggage-masters of the different roads, as they requested that they be permitted to do the work, as they were responsible for the baggage and would be obliged to oversee the work and look after checks and reshipping. This, of course, is done under the direction of the sanitary inspectors; but we are obliged to pay the men for this work, and they are subject to our orders. In this connection I would like to inform you that the railroad authorities of the Central Vermont, the Grand Trunk, the South Eastern, and the Passumpsic have given us every facility to inspect passengers, baggage, and freight, and have assisted and supported our inspectors by every means in their power, and deserve the thanks of the service and the community generally.

"The inspection of trains is a difficult work, but it is being done as thoroughly as it is possible to do it. The inspectors are doing their work well, as I believe the result will prove. I have been with each inspector in making his trip to Canada and return, and am satisfied that all understand their duties, and are doing them well and satisfactorily to all intelligent and unprejudiced persons."

The Suffolk District Medical Society.—At the regular meeting of the Gynæcological Section, held in Boston, on Wednesday, November 18th, the following papers were read: "An Unusual Case of Hydatids complicating Labor," by Dr. W. A. Dunn; a translated account of "A Successful Case of Cæsarean Section," performed on a Japanese woman by a young woman recently graduated from an American medical college, and who went to Japan as a missionary, by Dr. E. W. Cushing; "The Use of Ether during Labor," by Dr. J. P. Reynolds, who reported seven cases of difficult labor in which ether had not only relieved the suffering, but had prevented a recurrence of complications which had occurred in previous labors —notably, post-partum hæmorrhage in three of the cases. He favored the general use of ether during labor, as did the gentlemen who took part in the discussion of the paper.

The Hempstead Church Restoration Fund.—Since our last issue we have received $10 for the fund from Dr. Fordyce Barker. The total sum now subscribed amounts to $31.

The Vacant Chair at the Long Island College Hospital.—We have assurances, if any were needed, that the greatest care will be exercised in choosing a successor to the late Dr. Armor. Indeed, the charter of the institution provides safeguards in this direction such as we should be glad to see imposed upon all our medical colleges.

Death from Football having been alleged in the case of a member of the freshman class at Yale College, who lately died suddenly of cerebral hæmorrhage, Dr. W. O. Ayres and Dr. W. W. Hawkes, who made the post-mortem examination, have furnished statements which seem to set the suspicion at rest.

The New York Society for the Relief of the Ruptured and Crippled held its twenty-second annual meeting on Thursday of last week. Eight thousand three hundred and seventeen new patients were reported to have been treated during the year.

The New York State Board of Health held a meeting in New York on Monday, at which the satisfactory character of the frontier inspection, under the direction of the Marine-Hospital Service, was clearly established.

The late Dr. Alonzo T. Keyt, of Cincinnati.—Dr. Keyt died suddenly, of cardiac disease, on Monday, the 9th inst., in his fifty-eighth year. He was a native of Ohio, and had been a practitioner in Cincinnati for upward of thirty-five years, his career having been honorable and successful. He was best known for the invention of a remarkably ingenious cardio-sphygmograph. At a meeting of prominent members of the Cincinnati profession, held on the Wednesday following his death, appropriate resolutions, drawn by Dr. A. E. Jones, Dr. William Carson, and Dr. W. H. Wilder, were passed, and remarks eulogistic of the deceased were made by Dr. C. G. Comegys, the chairman of the meeting, and by Dr. Carson, Dr. Dunn, Dr. Jones, and Dr. Kemper.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 1 to November 14, 1885:*

McClellan, Ely, Major and Surgeon. Leave of absence granted in orders, Cavalry Depot, Jefferson Barracks, Missouri, Octo-

ber 30th, is extended seven days. S. O. 254, A. G. O., November 4, 1885.

Ebert, R. G., Captain and Assistant Surgeon. Ordered from Camp Grant, Riverside Park, New York city, to Fort Hamilton, New York Harbor, for duty. S. O. 237, Department of the East, November 5, 1885.

Bushnell, G. E., First Lieutenant and Assistant Surgeon. Assigned to duty at Camp Grant, Riverside Park, New York city. S. O. 237, Department of the East, November 5, 1885.

Baily, E. I., Colonel and Surgeon. Relieved from duty as Attending Surgeon, San Francisco, Cal., and ordered for duty as Medical Director, Division of the Pacific and Department of California. S. O. 260, A. G. O., November 11, 1885.

Norris, Basil, Lieutenant-Colonel and Surgeon. Ordered for duty as Medical Director, Department of the Columbia. S. O. 260, A. G. O., November 11, 1885.

McKee, J. C., Major and Surgeon. Ordered for duty as Attending Surgeon and Examiner of Recruits, Boston, Mass. S. O. 260, A. G. O., November 11, 1885.

Vollum, E. P., Lieutenant-Colonel and Surgeon. Ordered for duty as Medical Director, Department of Texas. S. O. 260, A. G. O., November 11, 1885.

Smith, J. R., Lieutenant-Colonel and Surgeon. Ordered for duty as Attending Surgeon, New York city. S. O. 260, A. G. O., November 11, 1885.

Alexander, R. H., Lieutenant-Colonel and Surgeon. Ordered for duty as Medical Director, Department of Arizona. S. O. 260, A. G. O., November 11, 1885.

Kane, John J., Captain and Assistant Surgeon. Ordered for duty as Post Surgeon, Fort Ringgold, Texas. S. O. 141, Department of Texas, November 4, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 14, 1885.*

Sayre, J. S., Assistant Surgeon. Detached from Naval Hospital, Mare Island, and ordered to the Omaha.

Dixon, W. S., Surgeon. Detached from Coast Survey Steamer Hassler upon reporting of his relief, Past Assistant Surgeon D. O. Lewis, and to wait orders.

Lewis, D. O., Past Assistant Surgeon. Detached from naval rendezvous, San Francisco, and ordered to relieve W. S. Dixon, Steamer Hassler.

Dungan, J. S., Medical Director. Ordered to naval rendezvous, San Francisco, to relieve Past Assistant Surgeon D. O. Lewis.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the week ended November 14, 1885.*

Wheeler, W. A., Passed Assistant Surgeon. To proceed to Ontario, Canada, on special duty. November 11, 1885.

Urquhart, F. M., Passed Assistant Surgeon. To proceed to Baltimore, Md., with steamer Manhattan, and then rejoin station. November 12, 1885.

Society Meetings for the Coming Week:

Monday, *November 23d:* Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement.

Tuesday, *November 24th:* New York Dermatological Society; New York Surgical Society; Medical Association of Central New York (semi-annual—Syracuse); Buffalo Obstetrical Society (private); Boston Society of Medical Sciences (private).

Wednesday, *November 25th:* New York Pathological Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society (conversational); Auburn City, N. Y., Medical Association; Berkshire, Mass., District Medical Society (Pittsfield).

Thursday, *November 26th:* New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); Harlem Medical Association of the City of New York; New York Orthopædic Society; Brooklyn Pathological Society; Pathological Society of Philadelphia; Roxbury, Mass., Society for Medical Improvement (private); Cumberland County, Me., Medical Society (annual—Portland).

Friday, *November 27th:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, *November 28th:* New York Medical and Surgical Society.

Letters to the Editor.

THE PROPOSED NEW NATIONAL MEDICAL SOCIETY.

———, Minnesota, *November 5, 1885.*

To the Editor of the New York Medical Journal:

Sir: Regarding the discussion relating to the formation of a National Medical Academy I desire to add my mite. My suggestion is that (*a*) each subscriber of a medical journal in the United States send to the editor of his journal a list containing one hundred names who he desires shall constitute the Academy; (*b*) the editors of the medical journals in the United States vote for three deans of medical colleges, who shall constitute a canvassing board to count the votes sent in by the subscribers, announce the result, and name a date and place for a meeting and organization for the successful one hundred.

Each editor sends a ballot, on which appear the names of three college deans, to the surgeon-general of the army, who canvasses the vote, and the three receiving the highest number of votes constitute the canvassing board. The surgeon-general then names a date and place of meeting for this board to canvass the general election of the subscribers. Each editor sends the lists received from his subscribers to any member of the board, who are to meet at the place designated by the surgeon-general, and count the votes; and the one hundred receiving the highest number are to constitute the members of the Academy.

When a physician subscribes for more than one journal and sends more than one ballot, the canvassing board is to decide, by lot or otherwise, which ballot shall be counted. Each ballot is to be signed by the voter; the subscribers to vote in one month and the editors in the next month.

This plan I submit to the readers of your journal for consideration. It appears to me more simple than the one suggested by your correspondent in No. 361, and would give every member of the medical profession a voice in the formation of a body to which he will ever after point with pride. This is offered "as a labor of love" by one of those who "have no hope of becoming members of the Academy themselves."

I am, fraternally, W. H.

Proceedings of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

Second Annual Meeting, held in New York, Tuesday, Wednesday, Thursday, and Friday, November 17, 18, 19, and 20, 1885.

The President, Dr. JOHN P. GRAY, of Utica, in the Chair.

Tuesday's Proceedings.

The Report of the Council recommended that papers which were to appear in the volume of "Transactions" of the association be not published in the medical journals previously.

The Treasurer's Report showed the total receipts for the year to have been $2,461; balance in the treasury from last year, $683. Deducting disbursements for the year, there remained a balance of $193. For the library fund, the surplus from anniversary subscriptions last year was $630, $315 of which had been placed to the account of the building fund. Excluding disbursements, there remained in the library fund $31; $80 had been subscribed for a binding fund.

Dr. FERGUSON offered some amendments to the by-laws, to be acted upon at the next annual meeting. They referred chiefly to abolishing the office of corresponding and statistical secretary, the appointment of a librarian by the Council, and the striking out of certain words as to the qualifications of new members.

The President's Address: The Relations of the State to Medical Science.—The PRESIDENT then read his address, in which he reviewed the educational policy of the State of New York, which was confined principally to supervision of the common schools and of the normal schools in which teachers for the common schools were trained. The duties of the Board of Regents were briefly referred to. Law schools, medical schools, scientific schools, etc., were corporations sustained by private contributions or their earnings, and were individual enterprises, receiving no grants from the State. He then asked the question, what legislative interference was proper with this class of institutions which represented scientific education and research. Whether the State itself should undertake such education as a public measure constituted a serious question in political economy, and for this State, for the present at least, that question had been answered adversely. Legislative control over the medical schools of this State was not demanded by public interest. It was not intended to dispute the power of the Legislature to regulate medical education and declare what should constitute a doctor in medicine; but the fact was that the Legislature exercised its power only in the way of fostering, protecting, and advancing the interests of medical science up to giving the best opportunities to schools for attaining this end, and at the same time as far as possible allowing the individual entire freedom of special study and of the means for acquiring a knowledge of medical science. The State had not adopted, and could not adopt, any particular school or system of medicine as against others. It was the part of wisdom to give the widest latitude to discussion wherever matters of opinion seemed to be in conflict. The giving to the physician certain powers which the State had conferred upon him was the highest indorsement which the State could give the profession. The State had left the cultivation and development of medical science to the medical profession alone, and had granted the right to incorporate societies and associations in order to maintain its unity of work, and for its elevation and progress. With regard to the services of the medical profession to the public, little need be said. The physician's services were sought for by the people in the same way that the services of the lawyer or any other member of the community were sought for. As to the matter of granting diplomas, and the control of this power by the State, the speaker's views were adverse to any such proposed change. The State did not even attempt to regulate the compounding and sale of drugs and nostrums. As the State had nothing to do with the teaching in the schools, so it should have nothing to do with the examinations. What possible efficiency such a board of examiners as had been proposed could have in benefiting medical science, the profession, and the people, did not appear. Such a change would transfer students who came to the medical colleges of New York from all parts of the country, and from foreign countries, to the schools of Boston, Philadelphia, and other cities. The schools had done excellent work in elevating the standard of medical study, and, while there was room for further improvement, to seek it in the guardianship of the State was an error. It was true also that the preliminary education should be better, and this demand also promised to be met as soon as the advance of the times would permit.

Reports of the Different Branches of the association were then read, in which it appeared that a large number of papers on different subjects connected with medical science had been read, and other work had been performed. The president of the New York County Medical Association, Dr. C. A. Leale, also read the report of the year's work of that society.

The Address in State Medicine.—Dr. ALFRED L. CARROLL, president of the Section in State Medicine, then read his address. He briefly reviewed state medicine, or sanitary medicine, as it had existed in ancient times, and said that many excellent rules were in force among the Israelites which would be of practical utility if adopted at present. State medicine, in its comprehensive sense, included all the medical interests of the State, but, in the popular estimation, the term had a narrow significance, being applied more especially to the practical administration of sanitary science for the protection of the public health. Even with this limited definition, preventive medicine had presented its claims with greater vigor than other specialties. Modern sanitation might be defined as applied physiology. The sanitarian should be primarily an accomplished physician, but he should add to his medical knowledge some theoretical if not practical knowledge of architecture and engineering. He should know how to detect defects therein and suggest the remedies. Dr. Carroll then pointed out some of the conflicting opinions of sanitary men regarding what constituted sanitary conditions. The superstructure of public sanitation had to be built upon the laws of personal hygiene. It followed that enlightenment in this direction must originate with physicians. As was the seed sown by medical schools so would be the harvest of public health. How had these schools fulfilled this condition? He would grant that many of them furnished the opportunities, for a pupil having means and ambition to make use of them, to gain the necessary education, but what was needed was an enforced education in all important branches, not leaving their study optional with the student. He named the studies and time required for study in England, and said that, while the work seemed formidable, it would also be seen that the knowledge to be acquired was not more than every physician should have when he came to discharge his duties to the public and to private patients. In his official relations Dr. Carroll had had an opportunity of learning what were the acquirements of persons who sought positions on boards of health, and the answers by men graduated from regular medical schools had often been absurdly erroneous. Now and then there were marked exceptions, even in remote country districts. He thought a weakness in the State and local boards of New York existed in the short term of office, and in the time spent in inducting new men into strange duties. The need of a preliminary education and of a higher

and more thoroughly enforced medical education was pointed out.

Tubercular Consumption; Is it ever Hereditary?—Dr. Henry D. Didama, of Syracuse, read a paper on this subject, in which he quoted the opinions of different authors on the subject of hereditary tendency, hereditary diathesis, etc., and also the results of post-mortem examinations by various pathologists, and said that in the examinations of the bodies of hundreds and thousands of fœtuses none had been found to have tubercle, which weighed very heavily against the heredity theory. He also quoted the statistics furnished by insurance companies, by which it appeared that the majority of cases of phthisis occurred in persons whose parents had not suffered from the disease. The following were the conclusions which the author reached: 1. That tuberculous disease was not inherited. 2. That, if a special tendency to the disease was transmitted, the term liability better expressed the idea than the term tendency. 3. That many conditions, such as poor and insufficient food, damp and impure air, stinted sunlight, and certain occupations, favored the development of the disease. 4. That two conditions were almost indispensable; abundance of bacilli and an inviting asylum for their development, whether the susceptibility was inherited or acquired. An important indication was to place the newly born child of a phthisical mother under the charge of a healthy wet-nurse, who should occupy a room entirely secluded from that of the consumptive members of the family. This gave an opportunity to strengthen the feeble constitution and to eradicate a liability to the development of consumption. If a syphilitic taint existed or was suspected, the author advised antisyphilitic treatment, not only with a view to cure the syphilis, but also with a view to strengthen the constitution and guard against the development of phthisis.

Dr. Thomas F. Rochester, of Buffalo, said that some years ago he made an autopsy on an infant which died three weeks old. He found one lung crammed with miliary tubercles, and in the other there was a cavity of the size of a hickory-nut. The mother was healthy; the father had died before the baby was born. In another case, in which the father died before the birth of the child, and the mother was a healthy woman, having no tuberculosis, the child died at eighteen months of age, having had for a long time before death every indication of pulmonary phthisis, and for a short time of tuberculosis of the vertebræ. In the light of these cases he could not help believing that, sometimes at least, phthisis was hereditary. He would admit, however, that many people had phthisis whose parents had been free from the disease. The paper was further discussed by Dr. Colvin, Dr. Pomeroy, and others.

Psoitis and Peripsoitis; their Pathology and Differential Diagnosis.—Dr. Simeon T. Clark, of Niagara County, read a paper with this title, in which he first referred to the paucity of the literature of the subject, and the difficulties attending a differential diagnosis, and then proceeded to give the clinical histories of three cases which had come under his observation. In all the cases there had been a history of traumatism. In the first case the patient, a woman without children, aged forty-three, had received a blow on the abdomen, which was followed by severe pain in the supra-pubic region, two inches from the median line. A hard lump was recognized by the physician who examined her, from which the pain seemed to proceed. Nothing was discovered by a vaginal examination. Dr. Clark saw the patient afterward, and became convinced that there was suppurative inflammation of the psoas. Pus was removed, and thirty-one aspirations were made before a cure was finally effected. The pus did not contain a trace of phosphate of lime.

The second case was in a young man, whose condition originated in strains during roller-skating. When he consulted his physician, Dr. Gould, he complained of pain in the region of the hip, and had a rapid, bounding pulse, and a temperature of 105° F. Afterward copious perspiration of an acid odor, etc., led to the diagnosis of rheumatism, but finally a boggy tumor appeared in the supra-pubic region. An exploratory puncture gave exit to foul gases, followed by pus. An opportunity to make an autopsy was afforded in this case, and a psoas abscess was found, which had led to denudation of the bone beneath. There was also some softening of the vertebræ, but it was evident that the disease had originated in the muscle, and not in the vertebræ.

The third case was that of a man who first attributed his difficulty to rheumatism, from which he had been a frequent sufferer, but it was learned that he had injured himself in the region of the psoas while throwing filled sacks upon a wagon. He complained much of pain in the neighborhood of the thigh. The pain was relieved by a local anæsthetic. A supra-pubic tumor developed, which, at a time when Dr. Clark had intended to open it, burst spontaneously into the bladder, and a quart of healthy pus was evacuated *per urethram*. Another opening for the escape of pus was afterward made above Poupart's ligament. Pus then ceased to escape through the bladder, and finally through the artificial opening, and the patient went on to complete recovery.

In regard to the differential diagnosis, stress was laid on the history of traumatism, on pain in the thigh and leg, on the posture of the patient, who avoided extending and rotating the leg, on the supra-pubic tumor, and on aspiration letting out laudable pus. In each of his cases the syringing of the pus cavity had been followed by washing out with a solution of carbolic acid.

Dr. Frederick E. Hyde believed that many cases of supposed vertebral disease were really cases of the kind related by Dr. Clark, and he urged with great earnestness the importance of making a careful search in suspected cases for a history of traumatism, for a pelvic tumor, and for pus, by the repeated use of the aspirator if necessary; for the train of evils following a change of the laudable pus which was first present into unhealthy pus was too long and serious to permit of postponement, with the idea that eventually the symptoms would demonstrate the case to be one of Pott's disease. If taken in the early stage, a cure could be effected and the bones would escape implication.

Dr. J. Cronin, of Buffalo, had seen two or three cases of psoitis, and said that in diagnosis valuable aid would be found in putting the patient under the influence of chloroform, flexing the thigh, and searching for fluctuation over the region of the psoas muscle. A history of traumatism was important in diagnosticating psoitis. Let the pus escape, he said, then keep the leg in the extended position, bringing the walls of the sac together, and union would rapidly take place.

Dr. E. M. Moore, of Rochester, thought that, where it could be shown that the disease had begun with a traumatism, it was unnecessary to try to explain its occurrence on the supposition of a tubercular inflammation; an acute disease might become chronic, and, of course, when this occurred there was a good opportunity for tuberculosis to develop. But the commencement might have been in fibrous tissue, and extension have taken place thence to the bone.

Note on Two Peculiar Conditions of the Mammary Gland was the title of a paper, by Dr. S. T. Clark, read by title.

Shock and the Effects of Injuries upon the Nervous System.—Dr. Charles W. Brown opened a discussion on this subject with a short paper, in which he described the symptoms

present in shock, and referred briefly to the explanations which had been suggested of its nature. He had seen a few cases of what had been termed "insidious" shock, in which the patients did not suffer pain in proportion to the seriousness of the injury, and were of a cheerful state of mind, although there was almost a diagnostic melancholy expression upon the face, which seemed to foretell death. He also referred to individual susceptibility, and said that some persons of fleshy habit and apparent health would succumb to a minor injury to which some others of delicate habit and nervous temperament would give way less readily. Shock was less marked in persons suffering from chronic disease, but such persons were less likely to regain strength and make a complete recovery afterward than those of previous good health who might be able to withstand the first influence of the injury upon the nervous system. There were two indications in treatment: the first, to modify the effects of the shock, and the second, to control excessive inflammation. The use of heat and stimulants received some attention.

Dr. Frank H. Hamilton, of New York, continued the discussion with a short paper, read for him by Dr. Berminghan. His remarks were limited to surgical shock, which might be defined as a general paresis of the nervous system induced by external violence. One point which received his attention was what was called railroad shock. Many of the symptoms which had been described as belonging to railroad shock were seen in certain cases of shock which occurred before railroads had come into existence. But, if we admitted that the introduction of railroads had brought into existence a particular kind of shock, he thought it was due to that sort of injury to the spinal column which was likely to occur in railroad accidents, resembling the cracking of the leash of a whip. In these cases he believed that the injury was not primarily of the nature of a shock resulting from commotion of either peripheral or central nerves, but that those structures which lay external to the spinal marrow and contributed more or less to its support and protection, of which the ligaments were the chief, were those which suffered direct injury, and from which inflammation subsequently progressed to the spinal marrow itself. As to the treatment of shock, reaction should be brought about by rest; in some cases by warmth, stimulants.

Dr. Edmund S. Arnold continued the discussion with a brief paper, in which he took the view that shock was due to an impression produced upon the sympathetic nervous system, tending to stop its function, and, in doing so, stopping nutrition of vital parts over which that system of nerves presided. Sudden death would occur if such influence was sufficient to entirely destroy the function of this system of nerves or ganglia, as in case of lightning stroke. Another illustration, he thought, was in death by hydrocyanic acid. If there was an influence upon the heart in this case, he thought it was directly due to suppressed functiou of the sympathetic system, which presided over its action.

Some general discussion took place, Dr. Kneeland, Dr. French, Dr. Moore, Dr. Arnold, Dr. Van de Warker, and Dr. Hendricks participating.

Insanity following an Injury of the Head; Cerebral Cyst; Operation; Recovery.—Dr. Carlos F. McDonald read a paper with this title, the case being that of a man who received a pistol shot in the frontal region, inflicted by his own hand. The man was sent to prison, where he developed symptoms of insanity, and had to be confined in a cell. For a considerable period of time, however, he had been required, and was able, to do prison duty, but manifested a passionate temper. It was decided to trephine at the seat of the wound, which was half an inch in diameter, a fourth of an inch in depth, located over the right first frontal gyrus, corresponding to the junction of the anterior and middle third, three eighths of an inch to the right of the median line. The patient was etherized, the wound was found traversed by dense fibrous tissue, and no bone covered the dura mater. A fine hypodermic needle was introduced, and nothing was withdrawn until the fourth puncture was made, when about two drachms of serum were withdrawn. The fluid contained a few blood-corpuscles, which were accidental. Nothing more was done than to close the wound with suture and dress it antiseptically. The patient, on coming from under the influence of the anæsthetic, was in his natural mind, and was greatly pleased with the relief from pain at the seat of the injury, and shortly afterward gave a satisfactory account of his case from the beginning, excepting for a period when he was unconscious. He went on to complete recovery, with permanent relief from cerebral symptoms except for a part of a day. It was learned that the physician who saw him after the shooting had removed the pistol-ball; he found no fracture of the bone and no spiculæ.

Discussion on Pneumonia.—Dr. Austin Flint opened the discussion with a paper in which he propounded the following questions:

1. Was acute lobar pneumonia a primary local inflammatory disease, or was it an essential fever, the pulmonary affection being secondary thereto and constituting its anatomical characteristic?

Since 1877, when he read a paper in support of the doctrine that acute lobar pneumonia was not a local affection, but an essential fever, that doctrine had been gaining ground. The view was supported by the following facts: 1. Acute lobar pneumonia was characterized by an enormous exudation into the pulmonary alveoli, and this exudation might be rapidly absorbed, leaving the tissues intact. This anatomical fact, he said, had no analogy in local disease. 2. Acute lobar pneumonia never persisted and became a chronic affection. 3. It was never referable to any appreciable local condition, nor was it possible by any form of traumatic injury to produce the affection. 4. Ordinary causes of local disease were not capable of producing acute lobar pneumonia. The traditional belief that the affection might be produced by cold was without foundation, and was being abandoned even by the Germans. 5. That a special or specific influence was invariably the cause of acute lobar pneumonia was rendered probable by its occurrence at certain seasons, its greater frequency in certain climates, and its occurrence at times as an endemic disease. 6. It differed from acute primary local inflammation in that at the outset there was a pronounced chill. 7. In the course of the disease the temperature and associated febrile phenomena bore no constant relation to the local affection. 8. Experience showed that acute lobar pneumonia responded better to treatment addressed to the fever than to the local affection.

2. What facts and rational grounds, with our present knowledge, could be cited in support of the doctrine that acute lobar pneumonia depended on the presence of a specific micro-organism?

Dr. Flint left this question for discussion to Dr. Janeway, but expressed his belief in a specific micro-organism as the cause of the disease.

3. What conditions or circumstances incident to acute lobar pneumonia tended to render the disease fatal?

The present or previous existence of certain other diseases rendered the prognosis more unfavorable, and certain conditions, as empyema, pulmonary gangrene, malarial miasm, etc., were more likely to develop in one who had been reduced by pneumonia. But of special conditions, rendering danger of a fatal issue in the course of the disease greatest, the author mentioned heart-clot and heart-failure.

4. Were there known remedies or therapeutic measures capable of arresting this disease, or of exerting a curative influence by either shortening its duration or conducing in any way to a favorable termination?

Dr. Flint had reason to believe that quinine had been of benefit in shortening or exerting a favorable influence upon acute lobar pneumonia. But he could not enter fully into a discussion of the treatment.

5. Was blood-letting ever indicated in this disease, and, if so, what were the circumstances indicating and contra-indicating this measure of treatment?

Acute lobar pneumonia tended intrinsically toward recovery. Treatment in general should be for special indications. He believed there were circumstances in which blood-letting would prove of benefit, and that benefit would be most likely to manifest itself in relief of oppressed heart-action. Contra-indications to blood-letting were, previous existence of enfeebling affections and the anæmic state. A plethoric condition and a bounding pulse were among indications for this measure. The collection of cases made some years ago by Lewes, in which there were twenty-eight deaths out of a total of seventy-eight cases in which blood-letting was resorted to, showed a high mortality; but the cases were not selected.

6. Was alcohol useful in the treatment of cases of acute lobar pneumonia, and, if so, what were the indications for its use, and how was its use to be regulated as regards the quantity given, etc.?

The author regarded alcohol as indicated wherever the supporting plan of treatment was required, wherever there was a tendency to asthenia. It should be begun tentatively.

7. To what extent was it safe and useful to employ antipyretic measures of treatment in cases of acute lobar pneumonia, inclusive of the cold bath, sponging of the body, or the wet sheet?

Dr. Flint spoke specially as to his experience with the wet sheet, which he had employed in three cases, with favorable results.

8. Did relapses of acute lobar pneumonia ever occur during or shortly after convalescence, and did this disease involve any special liability to other diseases or sequels?

The first part of the question the author answered in the negative, and said this fact was in favor of the view that the disease was an essential fever, for local diseases had relapses. But one attack did not exempt against subsequent attacks.

The first question propounded was discussed in brief papers by Dr. Didama and Dr. Ross; the second by Dr. Janeway, who expressed regret at having been unable, on account of sickness, to make further personal investigations regarding the influence of a micro-organism in the causation of pneumonia. He gave a synopsis of the literature of the subject. The third question was discussed by Dr. W. H. Robb and Dr. H. M. Biggs; the fourth by Dr. T. F. Rochester and Dr. E. Van de Warker; the fifth by Dr. S. T. Clark and Dr. C. S. Wood; the sixth by Dr. John Shrady and Dr. E. D. Ferguson; the seventh by Dr. G. Griswold, Dr. C. G. Stockton, and Dr. W. S. Fuller; the eighth by Dr. J. G. Orton.

(To be concluded.)

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of September 15, 1885.

The President, Dr. J. A. McCorkle, in the Chair;

Dr. Z. T. Emery, Secretary.

Hospital Obstetrics.—Dr. Charles Jewett read a paper with this title. [See page 565.]

Dr. Stuart remarked that there were several points of special interest in the paper, first as to the very excellent remarks upon the application of the forceps, and the particular reference as to slow delivery. He had been in the habit, as some of the members of the society probably remembered, of using the forceps very frequently, and he had read a paper some years ago advocating the use of the forceps in delayed labor. He had modified his views somewhat in that respect, but he had grown more and more to see the value of what Dr. Jewett had said in regard to slow delivery when it was compatible with the safety of the patient. He was glad to know that there was not prevailing at the Long Island Hospital one form of fever which had prevailed all over the country, and which raged somewhat fiercely in New York for some time, namely, the fever of douching the vagina with antiseptic solutions, thus alarming the patient to a greater or less extent for fear there might be some germs of disease lurking about to cause her death by puerperal septicæmia. He was glad to know that the staff of the hospital did not insist upon that method of treatment. But it was important to have the forceps always ready, in case delivery by that means was found to be necessary. Referring to the treatment of abortion, he thought the reader might have made more of it. There was no procedure of more importance to the obstetrician than the clearing of the uterine cavity thoroughly under such circumstances. Midwives might attend cases of *labor* and no harm result therefrom; but they could not attend cases of abortion with impunity, and the very best physician was often at a loss how to proceed. It would be remembered that, during the first three months of utero-gestation, the union between the membranes and the uterine wall was very intimate. That was necessarily the case from the anatomical and physiological conditions existing at that time. It was for that reason, it seemed to him, that the treatment of abortion was so little understood by so many of the profession; and those who were in the habit of seeing cases of neglected abortion were those who were most aware of the fact that they were not properly treated. On account of this intimate union between the uterus and the fœtal appendages there was danger of hæmorrhage. The physician in attendance was sent for, perhaps, to find that the ovum had escaped. He found it entire in the bed, or in the vessel under the bed. He made a hasty examination of it and its appendages, and concluded that everything was satisfactory. There was no marked hæmorrhage at the time, and he went away feeling that the patient was not losing more blood than was normal under the circumstances. He came back day after day, inquired upon that point, and found that there was more or less hæmorrhage. The general practice of those who attended such cases was to go away and come again and keep on coming! There were physicians present who had had cases come to them from the hands of other physicians that had been going on for weeks after the ovum had escaped, the patients having become thoroughly bleached—losing arterial blood all the time. The only way to treat an abortion was that mentioned in the paper—by making a thorough and complete evacuation of the uterine cavity at the time the abortion occurred and by the use of the means specified. The profession was indebted to Dr. Skene, he believed, for the suggestion of the use of Sims's speculum in the performance of operations in the lying-in room. The use of Sims's speculum by Dr. Jewett showed its great advantage.

Dr. Palmer had noticed in every case, with the exception of two or three, that he had attended in his own private practice and in that of others, that there had been an elevation of temperature on the second, third, or fourth day, sometimes accompanied with a cessation of the lochial discharge, douches having been abstained from. He attributed this to retrograde metamorphosis taking place in the uterus, and an absorption of

the effete material. Again, on the third day, about the time of the establishment of the secretion of milk, he had noticed this same elevation of temperature, which subsided upon the full flow of the secretion. In the cases attended by him the douche had not been used in any way. When there had been a total disappearance of the lochia, he had simply used hot-water compresses over the vulva. In every case there had been a good recovery. He had seen no septicæmia.

In reply to a question by Dr. Thallon, Dr. JEWETT stated that the strength of the nitrate-of-silver solution used by Credé was two per cent.

Dr. CHASE asked Dr. Jewett's opinion regarding variations of temperature after labor as evidence of complications. What was the normal range of temperature in childbed?

Dr. JEWETT referred to certain observations upon this point by Dr. Napier and by Dr. Macdonald, which had appeared in the "Edinburgh Medical Journal" within a few years. He believed, with Napier, that 99·5° F. should be regarded as the physiological limit during the first four days following labor, and 99° thereafter. Higher temperatures, while they were more frequently due to trivial causes, rather than to sepsis, always demanded investigation. The thermometer afforded the most important evidence of the patient's condition.

A member asked whether it was Dr. Jewett's practice to use chloroform in normal parturition. The question had been suggested by the large percentage of lacerations. The use of chloroform he thought helped to prevent perineal injuries.

Dr. JEWETT replied that he gave chloroform as a routine practice during the second stage. He believed humanity demanded it, and that there was no scientific objection to it. Indeed, there were scientific considerations in its favor. Many physicians did not agree with him. They saw bad effects from chloroform; inertia during labor and relaxed uterus after labor. He thought the disadvantages of chloroform insignificant if it was not given too freely. His method was to allow a few whiffs during the acme of the pain, often pushing the anæsthesia nearly or quite to the surgical degree for a few moments as the head passed the vulva.

Membranous Dysmenorrhœa was the title of a paper read by Dr. ALEXANDER J. C. SKENE. [See page 561.]

Dr. ROCHESTER asked whether Dr. Skene felt as if he really had seen appreciable benefit from any mode of treatment, or whether it was a matter of some doubt if the treatment had had anything to do with it.

Dr. SKENE replied that he thought his histories of cases covered that ground, but he could answer that question more fully by stating that for a long time he had been positive that he did some harm and not much good by local or general treatment or both, employed on the theory that the trouble was inflammatory, and was sure of that point; and the next was that he did not remember a patient who got well without treatment, or in spite of treatment. When left alone they generally went on from bad to worse. There were those that recovered apparently for a time, but there was a recurrence again and again. Sometimes by a change of location or of circumstances the general health would improve and the patient would recover, and some might remain well. Since he had adopted the treatment given in his paper a large percentage recovered. Take the case treated by Dr. Barker, which was only one of a number that showed the value of the treatment. In conversation he (Dr. Barker) had told the speaker that he produced much benefit with the method of treatment which had been advocated in the paper. He had been using it for years. The speaker believed that by a mode of treatment based on true pathology much had been accomplished and many cures effected, not alone by him, but first by Dr. Barker.

Dr. ROCHESTER had had one patient suffering with membranous dysmenorrhœa whom he had treated constitutionally only, in March last, without applying local treatment. She afterward married, and had had no dysmenorrhœa since. That was the reason for his having asked the question.

Dr. SKENE asked if the patient had borne children.

Dr. ROCHESTER said she had.

Dr. SKENE would say, then, that the doctor did not cure the patient, but that she was cured by pregnancy.

Dr. ROCHESTER said that that was what he meant to imply.

Dr. SKENE did not wish to pass that point so lightly, but would like to add that patients might recover after having become pregnant.

Dr. STUART said there was a little confusion in his mind as to the point of there being ovarian irritation, and the use of local applications to the uterine cavity. If the trouble was, as the reader would hold, due to ovarian irritation, he could hardly understand the philosophy of the local applications to the uterus except for a diseased condition of the uterus that might exist. In the two or three cases that he had thought of as Dr. Skene had been reading his paper, he could not recall them fully enough to speak of them distinctly, except in one instance, and that was only a temporary trouble, lasting for but two or three menstruations. That patient recovered without local treatment. He was satisfied that this was a case of conception, and that there was an exfoliation of the decidua vera. This lady had no uterine disease whatever, and had never had any form of leucorrhœa and no disturbance of the menstrual function except these two or three attacks. Attention was given to her general health and she recovered. The cast that was thrown off at one of these periods was a perfect specimen, and would have served for the original of the reader's description in the paper. He rose simply to ask the question as to the philosophy of the local applications.

Dr. SKENE looked upon the criticism as a very pertinent one. He would simply say that, while derangement of nutrition was no doubt produced originally from the ovarian irritation, the order of pathological events simply followed the ordinary rule—that *a disease might be caused by some extrinsic disturbance, and, after the cause was entirely removed, the disease might continue.* To illustrate: We very often observed mental affections which could honestly be traced to some pelvic disease; and yet, the pelvic disease being entirely remedied, the brain trouble produced thereby continued. We saw the same thing in some forms of nervous dyspepsia—ovarian dyspepsia; after the removal of ovarian trouble the disease (dyspepsia) continued. So he believed that, even after we removed or quieted the ovarian irritation, this *habit* of irritation or brain or gastric disease might go on; and that was the occasion for the local treatment. Recent pathologists had proved that the investing membrane of the ovaries was exactly like the endometrium, the only difference being that the Graafian follicles were closed, while the utricular glands were not. (See an article by M. P. Jacobi, M. D., begun in the January number and continuing up to this time in the "American Journal of Obstetrics.")

PHILADELPHIA PATHOLOGICAL SOCIETY.

Meeting of October 22, 1885.

The President, Dr. J. C. WILSON, in the Chair;
Dr. W. E. HUGHES, Recorder.

A Comparison of the Changes in Arteries after Ligature and in the Ductus Arteriosus and Umbilical Arteries after Birth.—Dr. J. COLLINS WARREN read a paper with this title.

After the ligature of an artery in its continuity, he said, the earliest changes noted were the formation of the thrombi within the vessel, and the development of a mass of inflammatory tissue, or callus, around the point of ligature externally. No perceptible cell action could be observed in the inner wall with low powers during the first week, although, under favorable circumstances, a proliferation to a limited extent of the endothelial cells near the point of ligature could be seen with high powers, and occasionally a few wandering cells might be found to have penetrated the walls of the vessel at the same point. In the second week the bundle of fibers of the adventitia which were surrounded and held by the knot had been absorbed, and the two ends of the vessel retracted slightly from one another, leaving the ligature imbedded in and partly disintegrated by the granulation cells. The walls of each portion appeared to form a complete *cul-de-sac*, and it looked at this time as if the healing process were complete, but it could hardly be said to have more than begun, as the vessel had not yet passed through what might be considered as the first stage of healing. The beginning of the second stage was marked by an unfolding of the ends of the vessel, the walls separating somewhat after the manner of opening of a bud, which permitted the entrance of a considerable quantity of the granulation tissue. A disintegration of the thrombus followed, and there were now a fully developed external and internal callus, a small fragment of clot still protecting the latter from the current. The ligature might be totally disintegrated and absorbed, or have become encysted, or, finally, have created a small abscess about itself which had discharged the fragments of thread through a sinus opening externally. The second stage was completed when the internal growth had reached the neighborhood of a branch. After this there was an absorption of the callus, which, as in fracture, was only a provisional structure, and eventually the two ends of the vessel were found held together by a slender cord of varying length. The walls of the vessel were slightly separated at each end by a cicatrix consisting of connective tissue externally, inside of which was another layer consisting largely of unstriped muscular fiber, the surface being covered within by a new endothelium. The cicatrix was always pierced by a vessel, which terminated in a number of capillaries ramifying in the cord. Here there was a scar made up of three layers resembling closely the three coats of the vessel. In the large vessel of an amputation stump there was a somewhat different series of changes. Soon after the ligation the end of the vessel might be seen imbedded in granulation tissue, and containing a thrombus of varying length. By the second week there was a marked change in the intima, extending for some distance above the point of ligation, probably to the first large branch, or to the origin of the vessel. Examined several months later, when the healing process had been completed, the vessel was found to be preserved in the form of a cord, running from the first large branch to the cicatrix of the stump. On laying open this cord the walls of the vessel were found preserved, the interior being filled with new tissue, leaving spaces occupied by one or more vessels. There had been a process resembling that known as obliterating endarteritis, by which the caliber of the blood-channel had been narrowed to an extent to adapt it to the diminished blood-supply. In this obliterating tissue we found comparatively large vessels, with new coats consisting of an endothelium, an elastic membrane, and also a new media. An erosion preparation would best represent the condition of the arteries of the stump at this time. The main artery would, after giving off its largest branches, break into a spray of smaller vessels, no one of which would predominate. A comparison of these two modes of healing with the changes seen in the arterial system after birth showed certain resemblances in the two processes. The ductus arteriosus, about the time of birth, differed considerably from the structure of the aorta and the pulmonary artery. The media was much thicker than in either of these vessels; it was thrown into irregular folds, which were increased at the time of birth and helped to narrow its caliber. The distinctions between the different layers of its wall were less marked than in other vessels. The lamina elastica was indistinct and in places apparently wanting; the media consisted chiefly of longitudinal layers of muscular fibers, a few circular bundles existing in the innermost layer. A few weeks after birth a greater portion of the walls of the ductus underwent hyaline degeneration, the inner or circular fibers of the media alone remaining, these being re-enforced apparently by a growth from the media of the larger vessels. At this time there was an active growth of long spindle-shaped cells with staff-shaped nuclei at the edges of the media bordering on the opening into the aorta; here was also a moderate thickening of the intima. Eventually the hyaline tissue became absorbed, and was replaced by a ligamentous band of fibers, which became continuous at either end with the media of the larger vessels. At the aortic end, in a longitudinal section, we saw the media slightly separated. At the point of the cicatrix, and between them and also continuous with them, were the longitudinal fibers of the ligamentum arteriosum. In this ligamentous tissue, and between the edges of the media, were numerous new muscular cells; nearer the surface there was a layer of thickened intima, which in the aorta had not only connective tissue in it, but also a deep musculo-elastic layer; in the center of the depression marking the site of the cicatrix a small vessel was given off, which penetrated into the axis of the ligament, where it either lost itself in a capillary network, or became continuous with a similar vessel coming from the pulmonary artery. These conditions closely resembled those which had been described as existing in the cicatrix of a large artery, after ligature, in its continuity—namely, the slightly separated ends of the media, between which lay the fibers of the ligament connecting it with the pulmonary artery, a new intima and a new growth of muscular cells, and finally a central arteriole. The only point of difference was the preservation of a layer of circular muscular fibers, which formed an outer wall to the ligamentous band, a much-needed support at a point exposed to great tension. Further protection was afforded by the oblique insertion of the ductus into the aorta, diminishing the pressure upon this particular point. At birth the umbilical artery, or that usually called the hypogastric artery, the portion within the abdomen, at its origin from the internal iliac, was a vessel of considerable size, being, in fact, a continuation of that artery. At its termination in the umbilical wound it had greatly contracted and was filled with clot for a distance of about one inch. The outlines of the various walls were not so distinct as in other vessels, and the elastic lamina for the most part was wanting. No special change was seen in the elements of the walls of the vessel except a slight accumulation of endothelial cells near the apex of the thrombus. A few weeks later there was a distinct growth on the inner surface of the wall up to its point of origin, the terminal portion having undergone a hyaline degeneration and obliteration for a short distance. The vessel had greatly contracted throughout its entire length, and its caliber was further diminished by the growth in its interior. Cross-sections taken from the superior vesical artery in adult life showed the media as a wall thick out of all proportion to the size of the vessel, and consisting not only of its original wall, containing longitudinal muscular cells interspersed with elastic tissue, but also of an inner circular row of cells which was provided with a well-formed elastic lamina. It seemed probable that the greater portion of the hypogastric artery had been preserved, the liga-

mentous band, which extended to the umbilicus, consisting of the obliterated extremity of that vessel, much elongated during the process of growth. The series of changes which occurred in the hypogastric artery after birth was closely analogous to that seen in the main trunk of an amputation-stump—a slight portion of each vessel was destroyed; both retracted and were attached to the terminal cicatrix by a band of fibrous tissue; both remained as pervious vessels, with thickened coats and narrowed caliber. In both the process was not unlike that seen in the so-called obliterating or compensatory arteritis. Arteritis hardly seemed a term applicable to the changes taking place in normal arteries after birth, nor could the alterations which had been developed through the whole length of a large vessel, extending a considerable distance from the original seat of inflammation, be strictly regarded as of an inflammatory nature. Might not the obliterating growths found to exist simultaneously in terminal arteries in widely remote portions of the body of the same individual also be regarded, not as of an inflammatory nature, but rather as a secondary and formative process, closely connected with disturbances in the mechanism of nutrition, designed to adapt the vessels to a diminished blood-supply?

Dr. S. W. Gross said that, in view of the fact that Dr. Warren's teaching seemed so directly opposed to that of other observers, he would like to have some points cleared up. He would, therefore, ask if Dr. Warren held, first, that, instead of the external coat, where it was included in the ligature, sloughing and coming away with the ligature, the pressure of the ligature set up an irritation which caused the adventitia to return to its embryonic state with a reconversion, after the ligature had cut through this, to connective tissue; and, second, whether the repair of arteries was brought about by the ingrowth of the cicatricial tissue, which he likened to provisional callus, together with some proliferation of the muscular cells of the media.

Dr. Randall said that, as the result of careful study of the subject, he had always found the clot present at first, and that it was honey-combed even in the first few days by the contraction of its fibrin; through the spaces thus formed the blood seemed to be circulating. Cells, either original white cells or of endothelial origin, occupied the walls of these cavernous spaces and seemed to sheathe them. The red cells early melted down into a homogeneous mass, furnishing the frame-work upon which the reparative tissue was built. The "plastic-clot" of some observers he had not seen—the new cells being distributed throughout the old clot as well as upon the vessel-walls, and not specially collected in the immediate neighborhood of the ligature. The obliteration of the vessel was accomplished by the growth and contraction of the trabeculæ of new tissue built upon the remains of the original blood-clot. Even close to the ligature he had not found the vessel-walls greatly altered, merely showing a great increase in the nuclei and in the number and size of the vasa vasorum, the lamina elastica being distinct and, as a rule, intact. Toward the end of the first month the new tissue consisted largely of spindle-cells, but careful staining had given no suggestion of muscular tissue. But, not having carried his study beyond the first month, he had no data upon this subject, since the development of muscular tissue was asserted to occur only at a later stage.

Dr. Formad was inclined to favor the views of Dr. Randall. The observation of Dr. Warren that the new-formed connective tissue played the most important part was to him entirely novel. He thought that probably pressure upon the artery from without, with consequent diminution in its lumen, might bring about a condition more analogous to the growth of fœtal life than to inflammation.

Dr. Mears remarked that we were liable to be confused in considering this subject by the presence of the blood in the vessel. So far as the process of healing after ligature was concerned, we might consider only the structures which entered into the formation of the vessel-wall, which was complex in character and composed of connective, yellow elastic, and endothelial tissues. Dr. Warren had given a very clear demonstration of cicatrization as it occurred in these structures after application of the ligature.

Dr. Tyson said the most novel feature, to him, in Dr. Warren's observations was the part played by the muscular tissue. This apparent increase in the muscular tissue he was inclined to believe was really only a proliferation of inter-muscular connective tissue. He was becoming more and more convinced that there was only one kind of inflammation—the interstitial. He feared that he might himself mistake a proliferating connective tissue with spindle cells for muscular tissue. It was true that new-formed capillaries and arterioles had muscular walls, but the development of these seemed to him to be a slower process. He had expected to find a process of repair in the ductus arteriosus different from that in an ordinary artery. This process he had expected would be a true endarteritis, for it seemed that the conditions of closure here were rather different from those in the ligaturing of an ordinary artery and in the umbilical artery, where also ligation was practiced.

Dr. Warren, in closing, said that, in cases where there was much breaking down, with little repair, there might be a sloughing of the external coat, yet in his experiments this part of the arterial wall had not sloughed, but had simply been absorbed by the granulation tissue, as the ligature itself was in some cases. In the normal condition even the elastic lamina was not a perfectly continuous plate; he did not refer to these breaks, however, but to numbers of little ruptures incident to the pulling of an artery out of the wound in the act of ligation; however, this need not necessarily occur. He had not attempted to identify anything like muscular tissue early; this could not be recognized till a permanent cicatrix had been formed. He had carefully eliminated all sources of error, and it seemed to him that in almost all cases there was a considerable number of these muscular cells. The layer was not always so well marked as in his diagrams; especially was this true of human specimens, but these had all been in alcohol for some years; of the fresh specimens he had selected only those in which he had considered the process complete. In a specimen which he had with him, through an opening in the lamina elastica cells could be traced from the muscular layer, those in the inside resembling exactly those outside. These facts, together with the fact that normally there were a few muscular cells inside of the lamina elastica, led him to believe in the proliferation of the muscular tissue. The disintegration of the blood-clot was accomplished by granulations growing inward from the callus, there being two sets of blood-vessels—one in the granulations, the other (blood-spaces, rather) in the clot itself. These united about the end of the first or second month.

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of September 24, 1885.

The President, Dr. B. F. Westbrook, in the Chair;
Dr. A. H. P. Leuf, Secretary.

Œdema of the Glottis; Tracheotomy; Death.—Dr. J. C. Bowker read the history of the case, in behalf of Dr. O. A. Gordon, who was absent.

"Thomas T., aged fifty, a laborer, strong and well nourished applied for admission to St. Mary's Hospital, September 2d, at about 5 P. M. He said he had suffered from a sore throat for

about a week and had been unable to swallow much solid food for two days. He was quite hoarse, and unable to open his mouth more than three fourths of an inch, making an examination of the larynx very difficult. There was quite a marked enlargement in the left submaxillary region. The temperature and pulse were about normal. He was sent to the ward and an external application of iodine was made. When I made the evening rounds the patient was walking about the ward in conversation with other patients. I advised him to go to bed, intending to make a more careful examination in the morning. At about 8.30 the same evening the orderly rushed into my room and said the patient was choking. I hastened to the ward and found him gasping for breath and very cyanotic. I tried to pass my finger into his larynx. Failing in that, I opened the trachea at once without dissection and dilated the opening with a forceps until the tube was inserted. Although the operation was done as quickly as possible, the man had ceased to breathe before its completion, and persistent efforts at artificial respiration failed to revive him.

"The autopsy, made by Dr. Leuf, the pathologist, revealed marked œdema of the glottis, the whole mucous membrane above the vocal bands being involved. There was quite a large abscess situated in the left tonsillar region. The heart was filled with venous blood, and the lungs were emphysematous. There was cerebral œdema. The other organs were found to be normal."

Dr. Wackerhagen asked if there had been any hæmorrhage.

Dr. Read wished to know the cause of death.

Dr. Bowker replied that death had resulted from asphyxia.

Dr. Leuf stated that he had found no blood in the trachea or bronchi.

The President desired to learn if there had been any brain symptoms.

Dr. Bowker answered that there had not been, and that the patient had been in the hospital only a few hours when he died.

Dr. Burge called attention to the difficulty of examining the throat, from fixation of the jaw on account of the swelling in the tonsillar region.

Strangulated Femoral Hernia in the Male.—Dr. A. H. P. Leuf presented a specimen that he had removed from the left side. The constricting ring was about 1·25 ctm. in diameter and adherent to the gut passing through it. About 8 ctm. of the ileum had passed the ring, remaining incarcerated behind the saphenous opening. The patient had been sick seven or eight days. His trouble began with obstipation. At first there was no pain, but afterward he complained of pain in the epigastrium, close to the ensiform cartilage. Cathartics and enemata were given, and subsequently he was dosed with opium to relieve pain. At no time did he have any uneasiness below the umbilicus. Intestinal obstruction was diagnosticated by the attending physician, Dr. Irish, and both groins were examined several times. The patient always made contemptuous objections to these investigations, because he referred all his trouble elsewhere and considered the doctor fanciful. Dr. Watt was called in consultation, confirmed the diagnosis, and recommended a continuance of the plan of treatment already adopted. Abdominal incision was not deemed advisable. There was considerable vomiting, and death was due to asthenia. There was no sign of peritonitis at the autopsy except a very few vascular injections of the peritonæum in the neighborhood of the ring. The extended gut was darker in color than the remainder, but by no means gangrenous. All the adhesions at the femoral opening were recent and easily broken down.

Dr. Leuf opened the discussion by stating that the attending physicians, had they operated, would have made the exploratory incision above the umbilicus, near the seat of pain, and he desired to know the opinion of those present about the advisability of extending the cut down to the seat of trouble, or whether it would be better to pass the hand down and free the gut by manipulating it bimanually—*i. e.*, pulling with the inner hand and pushing with the other.

Dr. Wallace thought that that would depend entirely upon the surgeon.

Dr. Wackerhagen said he would *always* make an exploratory incision below the umbilicus, regardless of the seat of pain.

The General Pathology of Fever.—Dr. Joseph Merzbach read a paper with this title. (See page 569.)

Dr. Eccles could scarcely agree with the essayist in the statement that mental work had but little effect upon bodily temperature. Ordinary thinking might show a meager effect, but intense mental excitement would cause marked elevation. In conditions of terror or apprehension, when there was a tornado of thought, it was no unusual thing for the person affected to break out in profuse perspiration. Elevated temperature meant increased oxidation or diminished radiation. A check of perspiration might give rise to elevation of temperature. The act of perspiring did not lower temperature. It was work done in evaporation at the expense of bodily heat. Conduction also aided in keeping down temperature. The irritating presence of non-excreted waste products might constitute a factor in causing fever. In most febrile conditions there was a sort of diffuse inflammation in which the whole system took part. Apart from the action of specific heat-centers, or even without nerve control, every cell might become an independent heat-producer. To the physiological psychologist attention was the subjective side of co-ordinating force, and might be expected to have some bearing upon a subject of this kind. When attention was turned upon the feeling that arose from any particular organ there were congestion and increased heat of that organ. A boy at play might forget that he had a stomach until he thought of food, when all of a sudden he became hungry. This was true of every function having a special sensation connected with it. A soldier might be severely wounded and the injured part bleed but slightly while terror and duty commanded his attention, but, so soon as these ceased and he considered the pain, profuse hæmorrhage would set in. The pain was the subjective side of the wound. Attention turned upon the pain meant that the highest nervous control of the body discharged its energy toward the source of that pain. *Dis-ease* was a disturbance of our feeling of well-being. The concentration of attention during health upon this feeling maintained it. When much of our body or the whole body became irritated from any cause, energy went forth to every disturbed part from the highest centers. Along the path whence the discomfort came the return-current would go as soon as attention was turned thither. Thus every heat-producing part might be released and a sort of physiological anarchy ensue. The essayist had made no reference to the reduction and elevation of temperature by therapeutic agents, a phase of the subject well worth considering. Antipyrine lowered temperature and the salicylates elevated it. Many other agents acted in one or other of these two ways.

Dr. Leuf had frequently noticed upon himself the effect of excitement due to overwork in causing a feverish feeling. He had never measured his temperature with a thermometer, but could give an idea of the increase of his bodily heat by stating that he had again and again taken seven to ten, or even more, goblets of ice-water during an evening, and all within two hours (from 9 till 11); and during this time he would suffer with throbbing of the temples, tension of the head and face, sometimes

tinnitus aurium, a dry, parched tongue and lips—in fact, the tongue sometimes being actually painful. These symptoms invariably followed concentrated and continued mental effort. Still he could not imagine with Dr. Eccles that mental concentration would account for all rises of bodily temperature, if only for the reason that so many imbeciles, idiots, and children had fever. In cholera, for instance, there was the greatest mental apathy, and yet a marked rise in the body-heat. The increased work done by the body in perspiring could not be adduced as a general explanation of the reduction of high temperatures, for there was in some conditions a very high degree of fever, with profuse perspiration, continuing for days. Oiling the body also lowered the temperature when it was above the normal, but not in all cases. There was a reduction resulting from a cutaneous application and without resulting evaporation. He would also object to calling a fever a "diffuse inflammation in which the whole system took part," because that would be impossible with the present use of the word inflammation. He agreed with the reader fully in the thought he had intended to express, but objected to the words used.

Dr. Ecoles replied that while children or idiots might not be able to do any complex thinking, they were subjects of terror and endurers of pain. On these simple sensations they could center their attention with considerable persistence.

The President asked if Dr. Leuf had ever reduced excessive temperature by oiling the skin?

Dr. Leuf rejoined that he had, and that too when the efficacy of the method could hardly be questioned. In these instances it had been employed either without the use of drugs or conjoined with placebos. He also replied to a previous question by the president, that he believed the efficacy of oiling was due to its lessening heat-production. This, it seemed to him, it did in two ways. It quieted the nervous system, like the chloral Dr. Read used in his cases; and it relieved the intense irritability and dryness of the skin by making it soft and pliable, and avoiding a great deal of friction. He believed that the one great, ever-essential factor in increased heat-production was a certain disturbance or varying set of disturbances in the visceral sympathetics, especially those of the abdomen. Here were located the centers of heat, and they generated this in superabundance in proportion as they increased their activity. Their activity was presided over and depended upon the visceral sympathetic. As everybody knew, the thoracico-abdominal sympathetic ganglia were connected with the outer skin by means of their numerous double connections with the spinal nerves. It seemed, then, that oiling the skin also allayed irritability of these ganglionic centers, causing them to act with more control in regulating the work of the trunk viscera—the heat centers.

Dr. J. D. Sullivan stated it as his belief that fever was a disturbance of nutrition due to the nervous system. The waste in fever must be due to an arrest of nutrition. He put the question, whether the delirium in fever was the result of increased heat, of a poison, of an arrest of nutrition, or of a condition of the brain. He believed it was caused by changed conditions of the brain. He then illustrated by citing instances from his personal experience, when during an attack of fever he had imagined occurrences which to this day seemed to him as real as anything he knew, so that he had only become convinced of his mistake upon the positive assurance from reliable sources that he was wrong.

Dr. Eccles replied that he could take no mental grip upon the words of the last speaker. To say that defective nutrition caused fever gave no idea of the *modus operandi*. If it could be shown that this defect in any way increased oxidation or retarded the elimination of heat already produced, it would be an acceptable hypothesis. As to the delirium of fever, a few simple experiments, such as he had tried, would cast much light upon its genesis. During the time our attention was centered upon the delightful feeling of comfort experienced when about to drop into sleep, if we divided that attention, delirium of a mild type might be produced artificially and studied by introspection. "Try to catch yourself going to sleep," he said, "and an *alter ego* will arise with whom most incongruous conversations may occur, and ideas quite foreign to the purely waking state will intrude themselves. While you are yet awake, absurd dreams will come up in your consciousness, and you will be quite aware of their absurdity. It is the result of divided attention—unconscious cerebration in this way pushes itself within the door of consciousness." Even in our waking state it often happened that we did and said irrational things if our attention was divided. The unfortunate occurrence that had happened to Mr. Am Ende, the Hoboken apothecary, in which morphine was substituted for quinine, was probably one of those quasi-delirious acts of a man with divided attention. It would not have been beyond possibility for such a thing to occur, and he know that a blunder was being committed, and yet feel powerless to arrest it. In the delirium of fever, currents of discomfort reached the highest nerve-centers from every direction. All these were subjectively perceived and the attention was distracted among them. Active cerebration resulted from them in the most disorderly manner. Attention allowed this chaos to intrude on consciousness.

Dr. Sullivan rejoined that, if it was possible to explain nutrition by chemical or philosophical means, he might be able to explain how its arrest caused fever.

The President remarked that Dr. Eccles and Dr. Sullivan viewed the question regarding temperature elevation from opposite standpoints. The former looked at it as a physicist, the latter as a vitalist.

Dr. H. N. Read would speak only on the influence of the nervous system on the temperature of ephemeral fevers in children. He had one case in mind that had shown this beautifully. A young infant suddenly became ill. There were no other disturbances than those common to fever. The temperature was 103° or 104° F. He gave chloral to control excessive irritability and the convulsions—*i. e.*, to reduce the nervous tension. After several hours the child was in a normal condition. Such cases were quite frequently met with, and the patients were well within from six to twenty-four hours after the administration of a nervous sedative. Often there was not even constipation. He believed that, if the proper apparatus was at hand to weigh these children before and after the attack, there would be found a diminution of weight from superoxidation. He thought that in these cases the fever was brought about by a change in metabolism due to insufficient nervous control.

Dr. Leuf remarked that the softening of viscera accompanying fever was of interest and worthy of consideration. He had noticed that the softening did not necessarily depend upon the length or severity of the fever. He had not examined these organs very often with the microscope, but they always had a fatty appearance. He thought the change in consistence was due to fatty infiltrations and degenerations, because they were always soft, pale, and greasy. In his experience, the heart had seemed most frequently affected, and after that the kidneys and liver. The kidneys were often so soft that they could easily be doubled over and made to touch end to end, and this too without cracking or fissuring, while the capsule was off. When the spleen was in that condition, it was very mushy and had a dirty pale-gray color. The capsule was, as a rule, wrinkled. The pancreas was also quite often in a similar condition, and, when so soft, had almost the same grayish color, but with a slightly

yellowish tinge. He had simply expressed himself on this point because there were many who did not consider these changes fatty, and who denied that fever was the causative agent.

Dr. Merzbach said, in answer to some of Dr. Eccles's remarks, that, as regarded the function of the skin, he had stated in his paper that it reduced the temperature in several ways, the most important of which was evaporation, then conduction, etc. The theory which gave the mind so much importance in the increase of body-heat he did not credit much. He had also seen very severe hæmorrhage from patients during anæsthesia and in other unconscious conditions, and supposed that everybody else had also. He could not see how arrest of nutrition would cause fever, but it certainly was a concomitant. It was well established that the nitrogenous elements were burned in greater proportions than other tissue elements were, as was shown in the increased amounts of urea passed through the kidneys. All of this waste was not accounted for by the burning of nitrogenous substances alone, as observation showed seven per cent. of the total decrease in twenty-four hours not accounted for. Thus the changes in the urine did not represent all the destruction. The cause of delirium might be indicated by the increased amount of phosphoric acid found in the urine. A similar condition was observed in chronic cerebral irritation or neuralgia. He did not think it necessary to suppose some foreign influence to be the cause of delirium. Hot blood might be sufficient cause. There was, for instance, a chronic excitability noticeable in peoples existing in hot climates. We all knew the excitability of the races of the tropics, whether civilized or uncivilized, and he supposed it was possibly due to the continuous irritation of the superheated atmosphere and its effects transmitted for ages from generation to generation.

The President said it was interesting that in fevers of the same height there was a great difference as to the amount or even presence of delirium—for instance, malarial and typhus fevers. Then the existence of heat-centers was of interest. Dr. Ott had recently shown quite positively that there was a heat-center just anterior to the caudate nucleus. Fever, too, was very often accompanied for days with profuse sweating, although the temperature remained very high.

Dr. Eccles asked how high the president had noticed the temperature under these conditions.

The President replied that he had seen the thermometer register 106° F. during continuous profuse perspiration, and just after marked sweating in typhoid fever he had seen it 104°; likewise in tuberculosis.

Dr. Merzbach, in closing the discussion, stated that he had alluded in his paper to the fact that high temperature alone did not always explain delirium, because in different fevers, as had already been stated, when the body-heat was the same, there was a great difference in the degree of delirium. He had not attempted to explain it, because it could not be done. The only way in which he could account for persistent high temperature during perspiration was by supposing the heat-production to be so great that the sweating could not wholly counteract it.

Miscellany.

The Cholera in Spain.—The "Gibraltar Chronicle" publishes the following: "From a letter," says the 'Times,' "which has just been published in a Swiss paper, written by the wife of a Swiss merchant settled in Spain, besides giving a vivid idea of the condition of that unfortunate country, shows how much medical men and Government officers have to contend with in their efforts to combat with the plague that is working such terrible havoc throughout the Peninsula:

"'The other day there died in a house not far from ours a widow, the mother of two daughters. She had been suffering for a long time from an affection of the chest, and, shortly before her death, a doctor was called in, who prescribed medicine and gave such directions for her treatment as he thought necessary. This was on a Saturday night, and on the following morning the poor woman breathed her last. No sooner was this known than a rumor went about that the medicine prescribed by the doctor contained poison, and was given to the widow in order that she might appear to have died of cholera. The elder daughter ran into the street like a maniac, shrieking "Scoundrel! scoundrel! where is the wretch who has poisoned my mother?" That was a terrible day for me, especially as Karl (the writer's husband) was not here. A great crowd gathered before the house of the dead and ours calling for the judge, and threatening the doctor with death. Then the body was taken into the churchyard in order that it might be opened. Just think; some of the people (as was afterward proved) killed a rabbit and said it had died after being given some of the physic prescribed for the widow. After the body was removed there came the judge, and also the druggist who had mixed the medicine, and, to show how harmless it was, the druggist took at a draught all the physic left in the bottle. The doctor also testified that it contained nothing whatever of a hurtful nature, and was really no more than a refreshing drink. When the widow's body was opened, moreover, it presented no choleraic symptoms whatever, but the lungs were very much diseased, and the cause of death was proved beyond dispute to be consumption. The excitement and uproar were, however, something terrible, particularly among the lower orders; they persisted in believing that the woman had been poisoned, and paraded the streets, declaring that they would force all the doctors to drink their own physic; and most of the patients of Dr. Antonio Espinosa (who prescribed for the widow) have thrown his medicine away, and he is bringing an action against the daughters for defamation of character. In the meanwhile the authorities have recommended the doctors to prescribe only pills, the popular belief being that pills can not be poisoned. This will give you some idea of what the people here are like.'"

A Dispensary Service for Mental Diseases.—The establishment of a service of this sort in Philadelphia, believed to be the first in this country, is thus announced by the Philadelphia "Evening Bulletin":

"At the last meeting of the managers of the Pennsylvania Hospital it was determined to add to the Out-Patient or Dispensary Department a new service for the benefit of the indigent poor who are suffering from the early symptoms of insanity, or insanity in its incipient stages. The managers have been led to create this addition to their already comprehensive service by the conviction that many persons in indigent circumstances do not receive that advice and medical treatment at a critical period when experience shows the greatest benefit from treatment may be expected. It is their observation, and that of all connected with hospitals for the insane, that, in consequence of delay from various causes, an undue proportion of cases lapse into a chronic and incurable condition, and in that state are brought to the hospitals.

"Public announcement is therefore made that the managers of the hospital have made arrangements for the commencement of the new service on Monday next, November 2d, at 3 P. M., in the Out-Patient Department, Spruce Street near Ninth, at which hour a physician will be in attendance. A physician will attend every succeeding Friday and Monday at the same hour and place until further notice. Chronic cases, and those requiring custodial care, will not, for obvious reasons, be received. The medical service will at first be rendered by the physicians connected with the Department for the Insane of the Pennsylvania Hospital. The work which is now proposed is of an experimental nature, and no conjecture can be formed as to the extent of the demand, nor whether any demand exists which will warrant the permanent establishment of a special department. If no demand for the additional service that has been provided shall, after a fair trial, be found to exist, it will be abandoned. But, if it shall appear, on the other hand, that such a department is likely to prove a great benefit to the class for which it is designed, some valuable experience may be

derived which may be suggestive hereafter. Every means for the prevention of insanity, or in the direction of a preventive measure, deserves most favorable consideration. If the measure shall appear to be a success, its friends anticipate that it may lead the way to enlarged operations in the same direction."

The Journal of Heredity is the title of a new periodical, published in Chicago, and edited by Mary Weeks Burnett, M. D., who modestly states at the outset that the journal does not "hope to solve all problems in heredity."

The Massachusetts Veterinary Association lately held its first meeting, says the "Boston Medical and Surgical Journal," and elected as officers Dr. Frank S. Billings, of the New York Polyclinic, president; Dr. L. H. Howard, of Boston, secretary and treasurer; and Dr. W. Dryden, Dr. W. T. Simmons, and Dr. J. M. Skally, all of Boston, members of the executive committee. The president read a paper on tuberculosis.

Luminous Signs for Doctors.—Speaking of an advertisement of these contrivances, the "Boston Medical and Surgical Journal" says: "As a rule, it is where the 'inward and spiritual grace' least abounds that there is the greatest ostentation of the 'outward and visible sign.'"

The Rex Disinfectant.—This is a preparation which acts by the slow disengagement of chlorine. It is the inventiou of an Ohio physician, and should not be confounded with the preservative solution termed "Rex Magnus." It consists of an earthy-looking, inodorous powder, to which commercial sulphuric acid is to be added. Chlorine fumes are at once to be recognized by the odor of the gas and by the ammonia test, but they are given off so slowly that, while efficient for purposes of disinfection, they do not render the air of the room irritating to the air-passages. Speaking from considerable experience, we have no hesitation in saying that the preparation is an excellent one for the purposes for which it is intended.

The New York Academy of Medicine.—The next meeting of the Section in Obstetrics and Diseases of Women and Children will be held on Wednesday evening, the 25th inst., instead of Thursday, the 26th, as Thanksgiving Day is appointed for the latter date. Dr. Joseph E. Winters will read a paper on "Diphtheria and its Management," which will be followed by a general discussion of the question "Are Diphtheria and Membranous Croup Distinct Diseases?"

Pasteur's Preventive Inoculation of Hydrophobia.—The Paris correspondent of the "Medical Times and Gazette," of London, states that M. Pasteur now adopts the following method. A rabbit is inoculated with a fragment of the spinal cord of a mad dog. The animal is affected with hydrophobia in the space of about a fortnight. A portion of its spinal cord is employed to inoculate a second rabbit, which also contracts the disease, but more rapidly; the spinal cord of this second rabbit serves to inoculate a third, and so on. It is observed that at each step of this process the intensity of the disease becomes greater, and the period of incubation shorter. When the spinal cord of these animals which have died of hydrophobia is suspended in a perfectly dry tube, its virulence diminishes by degrees, and at last disappears. A collection of these spinal cords, some of them entirely stale and powerless, others more fresh and active, others again quite fresh and extremely active, are always kept in readiness. To render a dog insusceptible of rabies, he is first inoculated with the stale and powerless specimens, then with fresher and more active ones, and lastly with the most powerful of all, when he becomes quite proof against the inoculation of rabies. Lately, a young boy, nine years of age, Joseph Meister, was brought by his friends to M. Pasteur's laboratory. He had been most severely lacerated by a mad dog, having fourteen bites in different parts of his body. M. Pasteur, in presence of the almost absolute certainty of death, inoculated the child according to his system; the first inoculation was made with a spinal cord fifteen days old on the 6th of July, sixty hours after the child had been bitten. Similar inoculations with virus of constantly increasing intensity were made up to the 16th of July, when the spinal cord employed was quite fresh. The child, having up to the present time, four months after the accident, exhibited no symptoms of hydrophobia, is considered by M. Pasteur as radically cured, and he has already recommenced the same method of treatment upon a young shepherd, who, in defending other boys, was cruelly bitten by a mad dog, which he killed upon the spot. The results of this new experiment will be communicated by M. Pasteur in due time to the Academy. With respect to the first patient, the writer remarks, it must be remembered —(1) That sixty per cent. of people bitten by mad dogs do not contract hydrophobia. (2) That the incubatiou of the disease is sometimes extremely long (cases have been known to occur two years after the bite). The experiment is not therefore absolutely conclusive, although it marks a great progress in the history of the disease and justifies in some measure the enthusiastic applause with which the communication was received.

The New Nomenclature of Diseases.—Referring to Circular dated July, 1874, adopting the Provisional Nomenclature of Diseases of the Royal College of Physicians of London as the official nomenclature of diseases, and to paragraph 310 of the Revised Regulations of 1885, the surgeon general of the Marine-Hospital Service, uuder date of November 7, 1885, informs the medical officers of the service that the revised edition of 1885 of said Nomenclature will be used on and after January 1, 1886, instead of former editions.

The Late Dr. Samuel G. Armor.—At a recent meeting of the Detroit Academy of Medicine the following memorial resolutions were adopted:

Whereas, It has been announced that Professor Samuel G. Armor, M. D., LL. D., an honorary member of this body, and for many years a resident of Detroit, died at his home in Brooklyn, N. Y., on the 27th ultimo, in the prime of his vigor and usefulness,

Resolved, That, while we bow in submission to the decree of Infinite Wisdom, yet we hereby express our sense of sore bereavement in his death.

Resolved, That the untiring devotion which our friend had exhibited in his chosen life-work, the large-hearted generosity which he uniformly manifested toward his brother physicians, and the delicate sense of honor that marked all his dealings with them, together with his thorough integrity and broad manhood, endeared him to the majority of our membership personally in life, and remain enshrined as his best legacy in death.

Resolved, That we extend our warmest sympathy to the great number who, in the death of Dr. Armor, mourn the loss of a friend and teacher.

Resolved, That a copy of these resolutions be sent to the family of Dr. Armor, to the Long Island College Hospital faculty, to the several medical journals of Detroit, and to the New York "Medical Record" and the "New York Medical Journal."

(Signed) Edward W. Jenks,
George P. Andrews,
J. F. Noyes,
Committee.

Dr. Kinloch on the Congress.—In a letter to the editor of the "Medical News," of Philadelphia, a member of the committee from South Carolina says:

"My attention has just been called to a criticism in the 'Association Journal,' of October 31st, by an officer of the ex-Committee of Arrangements for the International Medical Congress, of a letter of my own, which appeared in your issue of October 10th.

"The effort reminds me so much of a cobbler striving to patch with flimsy material his originally bad work, that I might complacently afford to stand in my old shoes. But, for the benefit of my professional brethren, who may, through inadvertence, be deceived, I will notice only the two points in the criticism which may seem to affect my position. My letter stands as the public record of my action in the committee.

"1. I am accused of having 'persistently endeavored to obstruct the proceedings of the committee' (at the meeting in New York on the 3d and 4th of September) 'by frittering away valuable time with trivial objections.' These objections of my own are on record, and need not be defended. No doubt they were annoying to some. But the author

of the complaint has inadvertently paid me a very great compliment, for which I am grateful. To 'obstruct proceedings' which I have shown to be irregular and prearranged by certain parties to advance their special ends, regardless of the unity, harmony, and well-being of the profession, can only be regarded by proper-thinking persons as a meritorious act.

"2. Next it is stated that I complained that 'a letter which he (I) forwarded to the temporary secretary was not read before the meeting of the committee in Chicago, or embodied in the report which was recently published.' My letter is referred to as on a par with two hundred letters received from other parties (not members of the committee), to have read all of which would have occupied the entire day The committee, it is stated, only directed that a letter from Dr. Austin Flint, Sr., should be read.

"The above is not a correct statement of facts. I was, together with Dr. Austin Flint, a member of the Committee of Arrangements, and did not, therefore, occupy the same position with two hundred persons who may also have written letters, but who were outside of the committee. I had, therefore, equal right with Dr. Flint. As a member of the committee, unable to attend the Chicago meeting, I sent my letter addressed to both the chairman and secretary, waiving the fact that they had usurped their positions. I had an equal, if not a better, right than Dr. Flint to express my views by letter. He was represented by a proxy. After this proxy took his seat in the committee, Dr. Flint was, for the time being, not a member of the committee. But, further, the proxy was there to step in as a permanent member of the committee when Dr. Flint, in accordance with previous arrangement, stepped out. Possibly, as I was not connected with this or any other previously arranged programme, my letter was unimportant, and Dr. Flint's alone was accorded a reading. Had I occupied a like distinguished position in the eyes of the managers, or been as available for promotion from the ranks of the committee to the highest office in the Congress, I might have been accorded equal rights with my illustrious friend.

"Still, I am satisfied with my present humility, and would not exchange this for the highest office bestowed by the committee."

The Health of Chicago.—By the Health Department's "Condensed Statement of Mortality" for October, it appears that the following deaths from infectious diseases were reported: 1 from small-pox, 1 from measles, 27 from scarlet fever, 81 from diphtheria, 30 from croup, 8 from whooping-cough, 1 from typhus, 33 from typhoid fever, 6 from cerebro-spinal fever, 5 from malarial fevers, and 32 from other zymotic diseases.

THERAPEUTICAL NOTES.

Digitalis as a Corrigent of the Effects of Quinine on the Heart.—Talma and van der Weyde ("Ztschr. f. klin. Med."; "Ctrlbl. f. klin. Med.") state that small doses of quinine exaggerate the diastole of both the auricles and the ventricles, without notably redneing the systole; but that large doses increase the diastole still more, and render the systole imperfect, so that suspension of the heart's action may occur in diastole. If digitalis is given in addition, however, the ventricular systole is rendered almost perfect, and the auricular distension at the same time moderated, which accounts for the good effects of digitalis in acute dilatation of the heart from quinine poisoning.

Hamamelis in the Treatment of Prostatic Enlargement and of Buccal Cancer.—Dr. Duncan J. Mackenzie writes to the "British Medical Journal," saying that irrigation of the bladder with a mixture of a drachm of tincture of hamamelis, half a drachm of carbolic acid, and about twenty-five ounces of warm water, arrested periodical hæmorrhages from the urinary passages and the rectum in a case of prostatic enlargement under his care, and so reduced the congestion as to enable him to discontinue the use of the catheter. In another case, marked palliation, including the control of a hæmorrhagic tendency, followed the internal use of hamamelis, the case being one of cancer of the tonsil and of the tongue.

Two American Species of Aconite.—In the current number of "Drugs and Medicines of North America," Dr. Roberts Bartholow, of Philadelphia, relates certain experiments with *Aconitum Fischeri* and *A. uncinatum*, and gives the conclusions that he has drawn from them. *Aconitum Fischeri* grows abundantly in the mountainous regions of the western section of the United States, and the author thinks it gives every indication of rivaling the imported drug in activity and value. There are, however, marked and fundamental differences between its physiological action and that of *A. napellus*, which may be stated as follows:

Aconitum napellus.	*Aconitum Fischeri.*
Affects sensibility and lowers the irritability of the sensory nerves.	Does not affect the tactile or pain sense, although it causes the characteristic tingling; and does not affect the irritability of the sensory nerves.
Paralyzes the end-organs of the motor nerves, the trunks, and ultimately the motor portion of the cord.	Does not affect the contractility of muscles or the irritability of the motor nerves, but paralyzes the motor centers of the cord.
Stimulates the vagus roots and slows the heart; after a brief stimulating action, paralyzes the vaso-motor center in the medulla, and greatly lessens the blood pressure.	Paralyzes the pneumogastric and increases the force and number of the cardiac pulsations; rather stimulates the vaso-motor center, and does not lower the blood pressure.

Both cause death by paralysis of respiration.

As regards *A. uncinatum*, the author thinks it is practically inert, although very large doses appeared to heighten the cutaneous and corneal reflexes a little in frogs.

Hydronaphthol as an Antiseptic.—At a recent meeting of the Philadelphia Academy of Surgery, Dr. R. J. Levis read a paper entitled "Notes on the New Antiseptics, Hydronaphthol and the Potassio-mercuric Iodide" (for proof-slips of which we are indebted to the courtesy of the "Philadelphia Medical Times"), in which he stated that his own experience with hydronaphthol in the wards of the Pennsylvania Hospital and in private surgical practice had confirmed the observations set forth by Dr. George R. Fowler, of Brooklyn, now in course of publication in this journal.

Hydroquinine as an Antipyretic.—According to Seifert ("Berlin. klin. Wchnschr."; "Union méd."), this derivative of quinine has antithermic properties resembling those of quinine and superior to those of salicylic acid and kairine, and produces neither delirium, ringing in the ears, nor headache. It appears to be rapid in its action and free from unpleasant effects, even on continued use, and it is to be recommended for children. It reduces the pulse and the temperature and causes free sweating. Its cost is about the same as that of quinine.

Thalline and Antipyrine in the Treatment of Febrile Diseases.—M. Jaccoud ("Gaz. hebdom. de méd. et de chir.") lately reported to the Paris *Académie de médecine* the results of his experience with these drugs in cases of typhoid fever, tuberculosis, pneumonia, and erysipelas, and laid particular stress on the transitory character of their effects. He believes that the course of the disease is not at all influenced by them, and that by using them we are merely playing with the surface-radiation of heat. Therefore he does not consider them solid additions to the materia medica.

Bismuth in the Treatment of Sweating Feet.—The "Union médicale" cites Viensse's recommendation of daily frictions with subnitrate of bismuth as a remedy for fœtid perspiration of the feet. The spaces between the toes should not be forgotten. The treatment is to be continued for about a fortnight. After the second or third friction, the sweating becomes less abundant, and the soreness rapidly subsides. The epidermis soon loses its white tint, and adheres more firmly to the subjacent derma, the excessive action of the sudoriparous and sebaceous glands diminishes, the perspiration becomes less irritating, and about the sixth day the skin resumes its natural look.

An Untoward Result of a Submucous Injection of Chloroform is reported by M. Blocq ("Progr. méd."; "Ctrlbl. f. chir."). Five or six drops were injected into the gum, as has been recommended for toothache, and immediately an intense and painful swelling of the face took place, followed by rather extensive sloughing of the mucous membrane of the upper lip and the gum, suppuration that lasted for months, and superficial necrosis of the maxilla.

Original Communications.

REMARKS ON EXCISION OF THE HIP.*

BY LEROY MILTON YALE, M. D.

AN apology is perhaps due to the society for again bringing up so well-worn a subject as excision of the hip. But, as it is one upon which surgical opinion is far from unanimous, its consideration must be always in order until the value of the operation is better settled than it yet is. The more recent views concerning tubercle and the rise of antiseptic surgery have stimulated the resort to excision in hip disease. Aseptic methods have now been long enough employed for considerable experience to have been accumulated as to their effect upon the ultimate results of the operation. This paper is the outcome of an attempt to ascertain from the periodical literature of the last six or seven years what this experience has been, and whether any conclusions could be drawn from it regarding the indications for resection in hip disease. Although tolerably familiar with the difficulties of the question, I confess I was somewhat surprised at the scantiness of the material which came to hand that was valuable for exact comparisons.

The grounds upon which resection of the hip is urged as preferable to non-interference are usually three:

1. That it directly saves life.

2. That it shortens treatment, and, by so doing, lessens risks both vital and functional.

3. That it gives better functional results.

There can be no manner of doubt that the operation often saves lives that otherwise must certainly have been sacrificed. Such operations *in extremis* have been aptly compared to tracheotomy in like conditions. Under such circumstances failures should not be counted. Every success should be esteemed a clear gain, and even prolongation of life and mitigation of suffering be reckoned in favor of the operation. About such resections there is probably no question. The inquiry is rather this: Comparing cases as nearly as possible similar, at what period, or under what circumstances, do the results obtained by excision become preferable to those gained by less radical measures? And it may be here remarked that a good deal that has been said regarding the relative value of early or late operations is rather beside the question, for there is little doubt as to their comparative success. The issue is between the operation at all and conservative methods, and the former is clearly indicated whenever it can be shown to give better prospects for life than the latter.

The value to be set upon resection, therefore, depends very largely upon what is held to be the natural tendency of the disease, and upon what success can be gained by conservative treatment. And right here, at the start, we find a divergence of views so wide as to go far toward explaining the unsettled condition of opinion regarding the operation. The most gloomy statements come from German authors. Thus Billroth gave the death-rate of his cases, some of which were followed after leaving the hospital, at 31¼ per cent., taking, if I understand correctly, all cases. Hueter,* from hospital records alone, gave 26¾ per cent. The two lists united give 28⅔ per cent. Nowhere else is the death-rate set so high when all stages of the disease are considered together. From reports for several years of the Orthopædic Hospital of this city, I find that the deaths and discharges on account of incurability together make an annual average of about 4¾ per cent. of all cases treated. Gibney's† statistics from the Hospital for the Ruptured and Crippled give for 288 cases a mortality from all causes of 12½ per cent. Taylor's‡ statistics, which give (deducting one case of violent death) 2 deaths in 93 cases, or 2⅙ per cent., can not be fairly quoted here, as they were drawn from a private practice among well-to-do people.

Although exsection has of late been done quite early in the disease, yet it would be obviously unfair to make any comparison between the death-rate of these collections of cases in all stages and the most favorable operative statistics. Again, although exsection is frequently done when destructive changes are recognizable in the joint, but before suppuration is evident, I know of no extended statistics of the corresponding cases treated conservatively. A few cases will be mentioned further on. But, regarding suppurative coxitis, we have more distinct expressions of the results of experience, and some statistics. Here, again, Hueter's estimates exceed others in gravity. While acknowledging the absence of exact information, he states that he should be surprised if statistics should show that more than 50 per cent. of cases that reach the "second florescence stage" (the stage of flexion, adduction, and inward rotation) ever were healed. And he further states his belief that "suppuration of the hip joint—if the cases in which a single small abscess forms and quickly closes again, and also the cases of scanty suppuration in the granulations of synovitis hyperplastica granulosa are subtracted—is a nearly absolutely fatal process."# Volkmann‖ is by no means so hopeless. Ollier△ thinks that "the greater part of the suppurative coxalgias of children may be cured by methodical expectation, aided by the resources of hygiene." Taylor lost 2 out of 24 suppurative cases, or 8⅓ per cent. This, as before stated, was in private practice. The committee of the Clinical Society of London◊ set the mortality of cases of suppurative hip disease, treated expectantly, at 33½ per cent. from all causes; or, leaving out causes unconnected with the disease, at 31·6 per cent. Cazin‡ gives the result in the cases of 80 patients treated at the hospital at Berck, sent from a Parisian hospital after they had failed to improve there. All but ten

of these were grave cases, and 5 per cent. were already albuminuric when received. The statistics cover five years; 55 per cent. were cured, 12½ per cent. died, 7½ per cent. were benefited, and the remaining 25 per cent. were not cured when removed. This remarkable success for cases of such severity may, perhaps, be not fairly introduced here, as the patients, although belonging to the hospital class, were at Berck under excellent hygienic influences, and were systematically treated.

Gibney,* out of 80 patients with hip disease cured without mechanical treatment, found 48 that had had abscesses. No percentage of mortality can be made here, as the total number having had abscesses that were treated is unknown; but this number of recoveries under a plan of the purest expectancy shows that suppurative coxitis can not be nearly so grave an accident as some have estimated it to be. As an offset, however, may be mentioned 19 patients recorded by Caumont,† treated conservatively, of whom 12 (63·1 per cent.) died.

From these discordant figures and opinions it seems to me fair to conclude that their disparity is not the result of the bias of different observers, but that in some communities or districts circumstances may so influence the course of the disease as to make an actual difference in the facts, as well as in the interpretation of them. To express an opinion, therefore, as to the average mortality of suppurative coxitis may be hazardous, or even presumptuous. Nevertheless, my own observations lead me to accept the more moderate estimates as the more nearly correct, and I should consider that the rate set in the Clinical Society's report was amply large; that is to say, that the death-rate would not exceed 30 per cent., even among the poor, at least as we know poverty in this great city. In private conversations, Dr. Gibney and Dr. Shaffer, of this city, both of whom have had unusual facilities for knowing the results of hip disease among the poor, expressed the opinion that the estimate I have given was very liberal, and would considerably exceed the facts.

Now, as to the death-rate of excision. Leisrink's often-quoted tables set it at 63·6 per cent.,‡ but this high figure is reached by setting aside all unhealed cases as worthless, which is a source of error, as many such cases go through the same course as unoperated cases and reach an ultimate cure, perhaps by ankylosis, after a long time. If all of Leisrink's cases had been included, his death-rate would have been 57·9 per cent. Sayre's# table gives 72 cases (two being still under treatment), with 25 deaths, or 34·7 per cent. Culbertson's tables contain 418 cases, with 174 deaths, or 41·62 per cent. If uncertain cases, 30 in number, are excluded, the percentage will be 44·84. All these collections contain cases observed for quite a long time, and this death-rate is by no means that of operation. Culbertson gives only 29 deaths as immediately resulting from the operation—that is, 6·93 per cent. of all cases. This is interesting as showing that even before the advent of antiseptic surgery the operation, as such, added but little to the general mortality from hip disease.

Many lists published since the beginning of antiseptic surgery contain cases treated in both periods, and often no attempt is made to separate them. Thus, Cowell,* in reporting 65 operations of his own, says: "I now perform the operation antiseptically," but the results are all grouped together. It does not appear that these cases were followed beyond the hospital. There were seven deaths among them, or 10·77 per cent. Three patients above eighteen years of age, all died. Of the 62 below eighteen years, only 4 died, or 6·15 per cent. Here should be placed the statistics of the Clinical Society's report, before quoted, which gave a mortality of 40 per cent., or, excluding deaths from causes unconnected with the disease, 37·7 per cent. Holmes's† list—given in his well-known Address in Surgery—of operations done in British hospitals belongs to the five years ending 1878, a period during which antiseptic precautions were coming into use. They should probably be considered as mixed operations. It does not appear how long the cases were followed, but, of 215 cases, 40, or 18·6 per cent., ended fatally, and 57, or 26·5 per cent., failed. Caumont,‡ whose statistics are commendable for the care with which patients have been traced for years after they left the hospital and carefully classified, records 42 cases, with 26 deaths, 61·9 per cent. Only 5, or 11·9 per cent., died from the operation. The remaining 50 per cent. were from progressive caries, amyloid changes, and tuberculosis. His death-rate before antisepsis was 66 per cent.; since antisepsis, 41 per cent.

Of operations entirely antiseptic, Volkmann# reports 48 with but 4 deaths, or 8⅓ per cent. Two only of these (from shock) were strictly deaths from operation; the third, after two months, was from thrombosis, and the fourth, after three months and a quarter, from hæmorrhage from ulceration of an artery, due to a suppurating scrofulous gland. Volkmann estimates that 8 or 10 would subsequently prove fatal from the progress of the disease, which would run up the death-rate to 25 or 30 per cent. Korff‖ reports 16 deaths out of 33 cases treated antiseptically (48·48 per cent.), the death-rate diminishing steadily as the methods were improved, being 75 per cent. when Lister only was used, 52·63 per cent. with a modified Lister, and 30 per cent. with a bichloride and salt gauze dressing. Grosch△ bases his statistics on 166 cases treated antiseptically; 120 of these were observed to the end, with 44 deaths, or 36·7 per cent. He divides his cases into three stages. The first contains those operated on with unruptured capsule and slight changes in the joint; the second, cases with abscess and fistulæ; the third, cases with long suppuration, extensive destruction of the joint with great debilitation. In the first class there was for children no death-rate; for the second, it was 24·1 per cent.; for the third, 67·5 per cent.

△ Inaugural Dissertation, Dorpat, 1882, Abstract in "Centralbl. f. Chirurgie," 1882, S. 228.

Further, he found that for the period 1876–'82, after antiseptic methods were well established, the death-rate was 9 per cent. less than for the period 1870–'75, in which these methods were forming. Quite recently Alexander* gives the results of 36 operations apparently all done and dressed antiseptically (chloride of zinc and Lister). One patient only died of operation (shock), 2·77 per cent.; 10 more from disease. Total death-rate, 30·55 per cent.

It will at once be seen that statistics gathered in such different ways, and to bring out different aspects of the question, can not be closely compared with hope of an exact result. But, if I have correctly apprehended the general import, it is this: that the mortality after resection of the hip joint has materially diminished since the introduction of antiseptic precautions, and that the diminution corresponds very closely to the death-rate formerly chargeable immediately to the operation itself. Take the extensive tables of Culbertson; setting aside uncertain cases, he had a total death-rate of 44·84 per cent.; deducting deaths from operation—6·93 per cent.—we have 37·91 per cent., which is very nearly the same as Grosch's—36·7 per cent. for 120 completed cases under antiseptic treatment. In other words, asepsis has almost abolished the risks from wound complications, and the death-rate is reduced very nearly to that from the uninterrupted disease when the operation has failed to arrest it.† And, as it has been shown that, in cases that heal, the period of healing is shorter than when antiseptics are not used, the danger of amyloid changes may be slightly lessened. Thus much has been gained by perfect antisepsis; in weighing the chances in any given case, we need no longer put much stress on the dangers of the operation itself, except, perhaps, the one element of shock, which the prolonged extirpation of diseased and suspected tissues, necessitated by the thoroughness of modern surgery, sometimes favors. It seems, then, fair to say that whenever the disease in its natural course assumes an aspect threatening to life, resection is indicated, provided none of the less radical operations—drainage, gouging, etc.—can remove the danger.

It has just been mentioned that very early operations, done while the changes in the joint are slight and the capsule unruptured, have given no death-rate, or almost none. But, on the other hand, the disease itself has practically no death-rate at this stage. Occasionally general or visceral tuberculosis may occur thus early, but rarely. Amyloid changes and exhaustion do not enter here as causes of death. It does not appear, then, that there is thus early any vital indication for excision. The early operation has been urged as vitally indicated in forestalling tuberculosis and the other attendant risks of morbus coxarius by cutting short the disease. If it could be proved that such prevention actually followed the operation, it would be a weighty argument. As Grosch points out, tuberculosis is still the commonest cause of death. König‡ maintains, as a result of a large experience in excision of all kinds—117 in three years and a half—that the hope for immunity from tubercular infection has not been gained by antiseptic resection. Of 25 deaths after his operations, 18 were from tuberculosis, and in addition nine patients, not yet dead, were hopelessly tuberculous; in all, 21·5 per cent. of his cases; and of 21 hip excisions, 10—47·6 per cent.—died of tuberculosis in four years. In the debate on König's paper some disagreement with his views was expressed, but Esmarch essentially confirmed them. Caumont* distinctly states that he found no preventive effect in his cases. Of 26 cases of scrofulous origin treated by expectancy, he lost 5—rather less than one fifth—from tubercular disease; of 12 resected, he lost 4, or one third. Others may have had better results, but the prophylactic effect can not be very decided if such marked exceptions occur.

Nor is it clear that destructive changes in the joint without evident suppuration often present a vital indication for excision. A vicious form of caries, characterized by great suffering and great destructiveness of tissues without much pus formation (caries sicca) is probably best met by resection. But of ordinary caries this is not true. It is a matter of common experience to find cases in which the destructive process is evidenced by the misplacement of the trochanter, which go through the whole course to recovery without any external evidence of suppuration. Caumont has taken the trouble to place such cases by themselves in his report. Of those treated expectantly, 25 per cent. died; of those exsected, 50 per cent.

It is not until suppuration has taken place that any vital indication for resec' ן appears. Even here I believe the dictum of Hueter† is ar too sweeping when he says: "I hold resection of the hip joint in coxitis to be indicated as soon as an extensive suppuration of the joint manifests itself, or as soon as the course shows that the termination in suppuration can be no longer prevented." Such a statement, however, is the natural outcome of his extremely gloomy views of the results of suppuration. If the opinion I have expressed as to the prognosis of suppurative coxalgia is anywhere near a correct one, resection is only indicated in a minority of cases. The indication comes not from the existence, but from the persistence, of suppuration. If it persists after the drainage of the abscesses and under the best hygienic resources the patient can command, particularly if fever attends the suppuration, then exploration of the joint is indicated, by incision or dilatation of existing fistulæ, with resection or a less extensive extirpation of the diseased parts, as the condition found may demand. And this should not be delayed after the system shows distinct depression from the suppurative process. To wait until the operation is the only escape from impending death is to err on the side of ultra-conservatism. I have not mentioned necrosis or sequestra in the joint, because under such circumstances some operation for the removal of the dead bone is imperative. Likewise, if perforation of the acetabulum with pelvic abscess exists, we have no resource but

* "Liverpool Med.-Chir. Journal," 1885, p. 289.

† At first sight it would seem as if more had been accomplished, but, as Grosch's statistics contain only early cases of a kind that scarcely appear in Culbertson's, the comparison is not quite upon an equal basis.

resection. True dislocation of the femur with suppuration of the hip joint is of very rare occurrence in ordinary hip disease, and the indication for excision often urged in this connection is rather orthopædic than vital.

A few words may be said regarding the second claim, that, namely, resection shortens the period of treatment, and that it diminishes the risks, both vital and functional. This is true of those cases that heal promptly and soundly, but only of such. Beside those that are fatal there is a long series of cases in which the patients neither die nor heal, but live years with persistent fistulæ. In Leisrink's tables 12·5 per cent. were "unhealed"; in Holmes's, 26·5 per cent. were "failures." Such cases now are often spoken of as "relapses." Asepsis favors prompt healing of the soft parts, but the union subsequently in many cases breaks down, and the old process is re-established under circumstances in no way improved. Just how frequent these "relapses" are I can not say, but they are often mentioned as "common." My own observations make them about 20 per cent. of all cases operated on. A friend who was in Kiel the past summer quotes Neuber as saying that "about half" of his cases relapsed. This refers, I understand, to the reopening of the wound, with tubercular granulations of its edges. Many of these ultimately do well after excision of the diseased parts.

Lastly, as to function. It is far from proved that resection gives better average results than a "natural" cure. In the question shortening is not the most important element. The shortening from resection is on the average greater than from natural cure, but not so very much. In a case not resected, but of such severity as to bring the operation into consideration, the growth of bone from the upper extremity will have been considerably retarded or arrested, according to the degree in which the epiphyseal cartilage has been affected. In a case resected the growth will be entirely abolished, and some bone already produced must be sacrificed. Ollier * points out that, although the total growth in length from the lower extremity of the femur amounts to about twice that from the upper, yet during the first four years of life the two ends contribute about equally, and that afterward the lower increases in activity until its work is, toward the end, about three times that of the upper. The prognosis as to length, then, will vary with the age at which excision is done, very early excision giving much the greatest ultimate shortening. The leaving of the greater trochanter does not much affect this relation, for what it contributes to growth in length is mainly above the joint and does not much increase the efficient length of the bone. The atrophy from inactivity affects the whole limb and is not materially different in cases resected from those left alone. If a resection was promptly successful, the advantage ought to be in favor of the operation, as permitting more speedy use of the limb.

Again, a useful joint in a lower extremity must be stable as well as mobile. And for most occupations security in the support of the trunk is more essential than motion at any one joint. Mobility with security at the hip after excision is only obtainable when very strong fibrous attachments exist between the pelvis and the remainder of the femur. The destruction from the disease and the necessary extirpation of affected tissues usually prevent the formation of attachments at once strong and flexible. Exceptions occasionally occur, and some very brilliant results have been obtained in which stability existed with very free motion.* Some very remarkable attempts at renovation of a hip joint have occurred, and interesting specimens have been described.† Nevertheless, as a rule, the motion, if considerable, is combined with such feebleness of support that the femur rides up and down on the pelvis in the act of walking. "Flail-joint," in the usual acceptation of the term as meaning uncontrollable motion in various directions, is rare, and I do not remember to have seen it. It is this insecurity that has led some operators (Ollier, Caumont) to urge that, if the operation is made very late, or in cases where much local damage has been done, if the patient must earn his living, it is better to strive for ankylosis rather than mobility. *A fortiori*, the ankylosis of a natural cure, the limb on the average being longer than after excision, will give for such persons a more useful limb. The compensating mobility of the spinal articulations, if the disease occurs in childhood, is often marvelous. The most striking instance I ever saw is No. 31 in Dr. Sayre's tables of excision; the motion took place in the lumbar spine, not only antero-posteriorly, but laterally, through a wide arc. Statistics (Grosch) show no better functional results for antiseptic operation than were formerly obtained. Functional reasons strengthen the indication for the substitution, whenever possible, of the simple extirpation of diseased tissues for formal excision in that they disturb less the relations of parts. These less radical performances are by the perfection of aseptic precautions rendered safe, and the large removals of bone formerly necessary to prevent accumulations of pus and septic matter seem no longer essential. In the same direction improvement of functional results may be hoped for by the employment in proper cases of the operative manœuvres in which a partial or temporary removal of the trochanter only is resorted to, the muscular attachments being little disturbed.‡

Further, it should not be forgotten that good functional results as to position and motion can only be obtained by prolonged after-treatment. Neglect in this particular constantly produces great deformity, and the care required to secure these good results quite answers the claim already alluded to—that resection is a short road to cure.

The conclusion, then, to which the foregoing brings us is, that exsection of the hip is indicated as a life-saving operation only; and that, as it has not been shown that it can save from any dangers except those consequent upon prolonged suppuration, it is, with rare exceptions, only indicated when the suppurative process has evidently reached a dangerous point, and can not be interrupted by any less serious operation.

TYPHOID FEVER
AS WE SEE IT IN CENTRAL NEW YORK.*

By H. L. ELSNER, M. D.,
SYRACUSE.

It is not the writer's object to give you a treatise on typhoid fever—its pathology, symptoms, and everything pertaining to that disease—in the space of this essay. That has been done by others whose accurate and keen observations have been given to the profession during the last twenty years. For the typical cases of typhoid we can find no better authorities than Griesinger, Liebermeister, Lebert, Murchison, and a score of others. All physicians who have been in active practice and seen a fair number of fever patients are well aware of the fact that in central New York but few of their cases follow the train of symptoms laid down in our leading text-books on typhoid fever. The cases that do follow exactly the descriptions of our leading authorities are rather the exception than the rule. Our cases are without the characteristic or typical temperature-curve. Their symptoms do not follow each other in regular order; in fact, their course seems different from the cases collated. The object of this paper is to lay before you the result of my clinical experience with the disease mentioned, and to prove to you by my records that our cases are atypical. In central New York you will have noticed that each year our fevers show some different phase; that each endemic has its characteristic manifestations, which cause it to differ from the typhoid of the previous year. Some epidemics, or even isolated cases, are influenced by a large and powerful malarial element; others are associated with complications changing the entire course of the disease, or markedly modifying it. Let us look, first, to the prodromes of the fever as we see it. In not a few cases of pure typhoid we have found our patients presenting, with a high temperature, following a more or less severe chill without having experienced a single prodromal symptom. In these cases there was no gradual rise to a higher temperature; but without prodromes we are at once plunged into a state of affairs which we would hardly expect in typical cases before the end of the fifth or seventh day. In one case, seen with Dr. A. S. Edwards, the patient was taken suddenly, on returning from his work, with a slight chill and a temperature of 104° F., all symptoms warranting the diagnosis of typhoid. Death took place on the sixth day of the disease. On post-mortem examination we found the enlarged spleen and mesenteric glands, with the characteristic appearance of Peyer's patches. These lesions at once proved the case to be typhoid beyond a shadow of doubt. Some of the cases do have the usual prodromes well marked; but the fact is established that, in a goodly number of our cases, there is an entire absence of prodromes; that in a few cases the gradual rise of temperature does not take place, but we have at once a high temperature followed by the characteristic rise and fall of the second week of typhoid. For the confirmation of this fact I would refer you to Charts K, O, and P. In children we frequently find a prodromal stage of catarrhal symptoms showing themselves in catarrhal bronchitis or broncho-pneumonia. I will not detail the history of patient M. L., but refer you to Chart Q, where there was a pneumonia followed by catarrhal bronchitis, and finally typhoid, with alarming hæmorrhage, on the thirtieth day of his sickness. In those cases not at first burdened with some complication we are safe in saying that violent chills are rather the exception than the rule. Most frequently there are sensations of cold, as "cold shudders" or "cold streaks." These sensations continue usually during an entire day, and are accompanied with headache. Violent chills occur in those cases with an intermittent tendency. In most cases we have the usual malaise, change of disposition, and listless and disinterested manner of the patient. Gastric disturbances are found in some cases during the first days of the disease, taking the place of other early symptoms. It is often difficult in these cases to give a positive diagnosis, for we may be justified, if there are also diarrhœa and abdominal tenderness, in diagnosticating gastro-enteritis, or some other abdominal disease with like symptoms. In these cases the epistaxis and facial appearance of the patient will aid in making the diagnosis. Gastric irritability continuing into the second and third week is a serious and often unfavorable symptom. In 60 per cent. of my cases there was an early diarrhœa; 40 per cent. of the patients suffered from constipation. This constipation is often obstinate, and, before resorting to any measure directed toward its relief, we are warned by the ileo-cæcal tenderness, and the other symptoms, that the patient has enteric fever.

A small admixture of blood is sometimes found in the stools during the first days of the disease, while in two cases I have found a free discharge of blood. In the first of these cases this bloody discharge was the symptom which led the patient to seek medical advice. In the second case there was a distinct venous hæmorrhage. These early hæmorrhages were found in cases of enteric fever with marked malarial symptoms. In some of our cases the diarrhœa was superseded by an obstinate constipation. In not a single case of typhoid disease have I been unable to detect tenderness in the region of the ileo-cæcal valve at some time during its course. This ileo-cæcal tenderness is not influenced by the severity of the disease or the amount of ulceration. *It is present in all cases of typhoid fever, however mild or severe the manifestations.* To this point I have given the closest attention in the examination of my patients, and it is one which I can positively assert. In typhoid fever, as we see it, epistaxis is one of the most frequent symptoms. In some cases it is mild, in others of sufficient gravity to require surgical interference. Early profuse nose-bleed is more frequently found in the severer forms of the disease. Nose-bleed profuse after the tenth day is always to be regarded as an ominous sign. There is no characteristic appearance of the tongue in our forms of typhoid fever. Some of our cases have led to the death of the patient after severe hæmorrhage or perforation, with a moist tongue from the first to the last day of the disease. In some of the most critical cases of

* Read before the Third Branch of the New York State Medical Association, June 9, 1885. A number of temperature charts were shown at the meeting, but, in order to save space, they are not published.—EDITOR.

typhoid that I have seen there has been a moist, red-tipped tongue throughout the course of the disease. Repeatedly we find the dry, hard, cracked tongue, bleeding at its edges, with sordes on the teeth. This appearance of the tongue is found in the graver forms of the disease. We are more likely to find intestinal hæmorrhage and other intestinal symptoms in a case with the dry tongue than with the moist tongue. The pulse goes hand in hand with the temperature during the height of the disease; after severe hæmorrhage it is more rapid, and even dicrotic. If the temperature is high the pulse is correspondingly high. I hardly think that any one of us could diagnose typhoid fever from an examination of the pulse, as there is nothing characteristic in it, any more than a physician could tell the true state of a fever patient without the daily use of the thermometer. The roseolar eruption is usually present; only occasionally do we fail to find it; when I have failed I have thought that it was overlooked. In some cases the eruption is quite profuse, but in the majority it makes its appearance at the time and in the manner mentioned in the books. In most of the cases of hæmorrhage I have noticed a fall of temperature, at some time during the twenty-four or thirty-six hours preceding its appearance, externally. Some of our patients seem to mend rapidly after a single hæmorrhage, but, when oft-repeated and large, they tend to debilitate the patient, and finally death may ensue from exhaustion. There is nothing noteworthy in the behavior of the hæmorrhage, and we pass to the consideration of the question of malarial influence on our forms of typhoid. To me it does not seem possible that a patient who has typhoid germs floating in his blood can not modify the symptoms arising from that condition by the admixture of malarial poison. I have thought that our typhoids were markedly influenced by a malarial element, and am now positively convinced by clinical experience. Often we are called to attend patients with typhoid who have gone safely through all the stages of the disease, each stage marked by characteristic periodicity. After convalescence has commenced, and our patients are doing nicely, we find them suddenly with severe chill, elevation of temperature, profuse perspiration and exhaustion following. This condition, if not treated, is likely to recur at a corresponding hour in the course of a few days. Quinine, liberally administered, is sufficient to overcome this trouble. If you will study the temperature-charts closely you will find that in numerous cases the temperature is higher at periods of the disease every other day; again you will find sudden and irregular elevations of temperature, with profuse perspiration. These patients have the roseolar eruption, some of them are accompanied with active delirium, and some have profuse intestinal hæmorrhages. Though the typhoid germs are in the ascendancy, the malarial element makes a profound impression, and influences materially the symptoms and course of the disease. Many of our cases begin with the symptoms of malarial continued fever, but before many days assume a typhoid type, show abdominal symptoms, and are then true cases of enteric fever. To decide the subject of temperature-curve, I will not longer weary you with detailed histories of cases; but have taken a number of cases from my daily record, and some from the hospital records, all of which have been faithfully kept, and appended them to this paper. I could offer many more charts, but they all show that we have no characteristic temperature-curve for typhoid fever as we see it in central New York.

Are there mild cases of typhoid fever? Does our scientific or any other treatment of these cases abort them? That there have been mild cases in our midst we can not deny. In the mildest the patients in my experience have not been considered convalescent before the end of three weeks, and in some the convalescence has been very slow. Our German *confrères* do not deny the possibility of mild cases of typhoid, and Jürgensen has written an able article describing them in Volkmann's "Klinische Vorträge," No. 61. We can not accept the mere statements of those who tell us that they abort typhoid fever; if we are called to see a case of fever of any kind, and our efforts are rewarded by a fall of temperature and return to normal of the patient, we can not consider that a case of aborted typhoid. The accurate, skilled, and careful observer will be cautious how he makes a diagnosis of any fever during the first week; and yet some of our friends would have us believe that they have cured their patients before *we* have had time to make a diagnosis.

To make the diagnosis of enteric fever we must be satisfied that there are abdominal lesions; without these there can be no typhoid. During the early days when we are called to see these cases the symptoms are vague; there may or may not have been nose-bleed; we could not say that a patient had typhoid fever because he had nose-bleed and slight febrile disturbance, all of which disappeared after a day or two of most energetic and polypathic medication. Those who abort cases of typhoid must first satisfy us that they have made the proper diagnosis; must instruct us in the manner of making such diagnosis, by pointing out the features of their cases which lead them to its early recognition and ultimate abortion.

In conclusion, I would say that it has not been my object in this paper to mention all the symptoms of typhoid fever; but it has been my endeavor to attempt at least to decide, by a careful examination of my records, a few points which seem to have puzzled and upset us for some time past in the discussion of the subject under consideration. I think I am safe in concluding that we do not have as a rule in our cases of typhoid fever a schematic temperature-curve, that they are markedly influenced by a malarial element, and, finally, that we are only justified in making the diagnosis of typhoid fever after a careful examination of the patient, noting each and every symptom, including thermometric measurements daily for at least seven days, the abdominal symptoms, roseola, ileo-cæcal tenderness, epistaxis, and then, by the coupling of all these symptoms and a careful consideration of each, a diagnosis can be made.

DISCUSSION.

Dr. Higgins: Mr. President, I can not feel at liberty to let this paper pass without saying a few words and giving my testimony to the faithfulness of Dr. Elsner's description of typhoid

fever as we meet with it in this vicinity. And, after a practice of thirty-five years in an intensely malarial region, I am more and more impressed that we have few cases of disease of any character that are not to some degree influenced by malaria. The point he made I have often observed, of the malaria manifesting itself after having passed the patient through that stage which I supposed placed him beyond the need of my care. In these cases distinct chills with marked regularity, requiring active and decided anti-periodic treatment for their suppression, were the main feature of what is often called relapse. I should say, however, that these cases were generally of that class that were allowed to go on from eight to ten days at the outset without active treatment, the most important period to modify the disease.

I look upon the paper as one of the most valuable and interesting I have ever heard upon this type of fever, and it interests me greatly from the fact that in this long period to which I have alluded our fevers have very much changed in character. We do not have now, as we did thirty years ago, those positive characteristics that definitely settled the question as to their nature. We do not find even those marked and distinct cases of old-fashioned "fever and ague." We find more prostration with a commingling of types belonging to different classes. Those fevers that were termed "bilious remittent" have disappeared, or at least the name has, and the word "typhoid" has the ascendancy over all others. I find very little true typhoid fever in the vicinity in which I practice, and that, almost without exception, masked by this subtle agency. In fact, I find so much of this malarial character that I am very cautious how I use the word "typhoid," and cases of that type often require many days to distinguish their true character. But with reference to abdominal lesions, those cases that develop that form of complaint, there can of course be no question. But what I wished to speak of particularly were those peculiarly malarial influences mingling with almost every disease which comes under my notice, and that too in all seasons of the year.

I simply arose, Mr. President, to make my acknowledgments to my friend, Dr. Elsner, personally, for this very able paper, it being so faithful a delineation of the disease as it has come under my observation, and being a subject of great public as well as professional interest.

Dr. Ross: I am very much interested in the doctor's paper; and while it seems that the type of typhoid fever mentioned by him is somewhat different from that which I am accustomed to see, I think, at least in half our cases, we have a *comparatively* typical run. There was another fact brought out by the doctor which is present in almost every case—that of roseola being found between the seventh and eighth days. Almost all of my cases have been between the eighth and twelfth days. Another thing: after an extremely high temperature, often running as high as 104° at the outset, and a pulse of 110 to 130 during the first twenty-four or forty-eight hours, the temperature will drop, then gradually rise, continuing as in a well-behaved case of typhoid fever.

A great many patients, as we see them, have constipation—perhaps one third; some are so much constipated that we are obliged at times to remove portions of hardened fæcal matter from the rectum with the finger; the tongue usually assumes a comparatively typical form.

In regard to aborting cases, I have seen cases begin with every symptom of typhoid fever—epistaxis, diarrhœa, tympanites, tender abdomen, and delirium, with a gradual rise of temperature for five or six days; then suddenly, whether due to treatment or to the natural termination of the disease, the fever drops to normal, other symptoms subside, and the patient is out within a week or ten days.

I had such a case not more than a month ago—that of a physician who resided in this city and was in the hospital here, I believe. He left the hospital and went into the country, where they were having, or had recently had, typhoid fever. He came home to Elmira and remained a few days, intending to go to an adjoining town to practice. The day before his intended start he was taken with every symptom of beginning typhoid fever. He had epistaxis, tympanites, delirium, diarrhœa, and a gradual rise of temperature for about five days, followed by a gradual abatement of all the symptoms.

Within seven or eight days he was out and about the house. I have seen such cases again and again, especially when we have had a large number of typhoid fever patients on hand.

Now, whether these are cases of *simple* fever or cases of aborted *typhoid* fever I am not prepared to say; the thought often comes to me that they *might* be, and there are good, well-read practitioners who believe this to be possible.

Of course we have no authority for expecting to abort a case of typhoid fever; neither do I wish to be considered as advocating such a theory. I would like to hear on this point the opinion of other members of the association.

Dr. Brown: My idea of typhoid fever is somewhat different from that of the last speaker. I believe that typhoid fever, strictly speaking, is a specific poison; that it starts out as typhoid fever, and I have contended that the idea of breaking up typhoid fever is simply ridiculous.

I believe when it is typhoid fever it is typhoid fever from the commencement; I believe that it is typhoid fever throughout; I believe if it commences as typhoid fever it will run a course as typhoid fever, and, according to my experience in a large number of cases connected with a school in Pennsylvania several years ago, and published in the journals, where the infection was caused by drinking-water. There were sixty-two persons taken sick within three weeks. The shortest duration of the fever was thirty days, and they ranged from that to forty and forty-five days. A large majority had hæmorrhage from the bowels and the cases were typical cases of typhoid fever. There were a few persons about the building and in that vicinity, who did not drink the water, who did not have the fever, but all that drank it had the fever. It was found that the drinking-water that they used was from a well that was about forty feet from a privy-vault that had been used for ten years. We found that the contents of the privy-vault had backed around into the well. The water tasted good and had the appearance of being good water. At the place there was an Artesian well that was one hundred and forty feet deep carried into the building, but the students and some of the teachers liked the surface well so much better that they would go out from their rooms and down to this well to get the water because they liked it. The deep well was, of course, all right. I sent samples of this water to Dr. Lattimer, of Rochester University, and he examined it and reported that it was swarming with animalcula; and so I believe that the large majority of cases of typhoid are the result of drinking water that is contaminated by sewage and bad air, and that in these cases of direct infection of typhoid fever there is no such thing as aborting them. These cases of continued fever spoken of I should regard as a different disease from true typhoid fever.

Dr. Bloomer.—Mr. President and Gentlemen: If this meeting had been held a year ago Dr. Chapin would probably have been here; and if he had been here he would have, no doubt, called attention to certain mental manifestations present in cases of typhoid fever.

There is no doubt that about the third week of typhoid fever there is a mental condition short of delirium, where the patient

is restless, apathetic, indifferent to his surroundings, when the question of testamentary capacity often comes up. Dr. Chapin related last year two cases published in the "American Journal of Insanity."

In one of his cases the patient, fifty-eight years old, a farmer, lying at the point of death, called his sons to his bedside and discharged some obligations to the amount of $6,000 or $8,000. He recovered from the fever; and a year afterward his sons were very much surprised by his asking them to have this obligation discharged; and he himself was quite confounded when he learned that the instrument had already been executed.

In another case the patient made a will in which he ignored the heirs in the male line, and his signature bore such a striking resemblance to that of the lawyer who guided the pen that there was a contest over the will. The late Dr. Cook and Dr. Chapin were called in as experts, who testified that in their opinion the patient was *non compos mentis*, and not in a disposing state of mind when he made the will; but the will was, notwithstanding, admitted to probate because it was executed in due legal form; and you all know what objections lawyers raise to the setting aside of an instrument that is executed according to the legal requirements.

Dr. Elsner: I merely wish to say that possibly the title, as it appears on the programme, is a misnomer.

The cases that I have described to you on paper have been seen in this county, and my experience with typhoid fever has been limited to this county. We consider ourselves in central New York, and, as I had no better name or title to give the paper, I gave it the title that appears on the programme.

Now, in regard to roseola. I think that you will find, in looking over the temperature-chart (for I have been particular in marking the roseola), that it did usually occur between the seventh and eighth day.

Then in regard to the abortive cases, and such cases as Dr. Ross mentioned. We all see them.

We are all called to treat just such cases as the doctor has mentioned. Some of the patients have active delirium at once, and some do not. We have a gradual rise of temperature, and, for a few days, imagine that we have a well-defined case of typhoid to treat; but our treatment is rewarded with success. Now, those cases can not be considered typhoid fever. One of the points that I wish to make in my paper is this: That we are not justified in making the diagnosis of typhoid fever unless we are sure that there are abdominal lesions. The tenderness in such a case may be caused by many other things. Typhoid ulceration may cause tenderness; ulceration in the region of the valve may cause it, and many other diseases that are not typhoid at all are associated with marked abdominal disturbance, yet can not be considered cases of typhoid fever. If we speak of aborting typhoid fever, such cases must be thrown out. We can not consider those as aborting cases of typhoid.

In regard to the mental state. I did not mention that in my paper, for I simply wish to impress upon your mind the leading symptoms of typhoid as we see it.

Dr. Bloomer has mentioned the mental state in some cases between the second and third week—that apathetic condition, that condition when the patient does not care whether school keeps or not. I think the much larger proportion of our patients are just in that very condition at that stage of the disease. The patient seems to lose all interest in himself or herself, however solicitous he or she may have been before; and I think there is a stage in typhoid, though I would not make this as a positive statement, at which these patients are not responsible for what they do, however clear they may have been during the entire course of the disease. I have repeatedly asked patients who have appeared perfectly rational throughout the entire course of the disease whether they remembered any facts concerning their sickness; much the larger proportion of them have told me that the time during the entire sickness seemed as if it had been a dream.

THE ANNUAL AND SEASONAL CLIMATIC MAPS OF THE UNITED STATES;

WITH A RULE FOR THE EVEN DIVISION OF CLIMATE,

BASED UPON THE AVERAGE OF THE COMBINED ATMOSPHERIC HUMIDITIES IN THE UNITED STATES.*

By CHARLES DENISON, M. D.,
DENVER, COL.

It is not the author's intention to write a new paper for the Climatological Association this year, but simply to complete his last year's contribution by a presentation of the graphical illustration of climatic statistics and of the divisions of climate in our own country, which was an important part of his last year's report. He can thus fulfill his obligation as "Committee on Climatic Elements, etc., Acting with the Chief Signal Officer," for the maps which are presented contain the different condensations of nearly five million signal-service observations, and for temperature, rain-fall, and wind movements—all the records since the Signal-Service stations were established. The result of studying so broad an area as is included within the boundaries of the United States is very gratifying in the presentation of a variety of climates and an amplitude between the extremes of moisture and dryness such as can hardly be claimed by any other government. Indulgence is craved for the introduction of the following descriptions of these climatic maps and the data they contain:

I. The Annual Map.—The annual map and tables are intended to give all the desirable annual averages of climatic statistics, and to graphically illustrate the most important of these—*i. e.*, the cloudiness of the air, annual temperatures, rain-fall, and wind—directions as to their prevalence and their influence upon the weather.

Cloudiness.—The relative cloudiness of the sky is one of the most important facts to be determined about the climate of different sections, for it is an estimate of the humidity of the atmosphere, which is but slightly affected by local peculiarities and the unequal radiation from the earth's surface. Particularly is cloudiness little affected by those faults of temperature statistics in cities, which are due to the greater heat there, and radiation from stone buildings, paved streets, etc. Besides, it is the most accurate estimate yet obtained of *the duration of sunshine.* The Signal-Service Bureau has no other reckoning of the time the sun shines than that obtained by inference—*i. e.*, if the sky is beclouded at two given stations thirty and sixty per cent. of the time, then the sun is assumed as shining seventy and forty per cent. of the time it is above the horizon at those places respectively. The annual average of sunshine can, accordingly, be approximated at from less than forty per cent. of day-time, in the northern Central Lake

* Read before the American Climatological Association, May 27, 1885.

region of the United States, to more than seventy per cent. along the eastern slope of the Rocky Mountains and in southern Arizona. This is a reasonable conclusion, and in accordance with the testimony of many observers. The sunshine is, therefore, represented by one hundred per cent. minus the per cent. of cloudiness of any given section. The proportion of cloudiness is telegraphed daily to Washington from all signal stations at 7 A. M., 3 P. M., and 11 P. M., Washington time. From these telegrams for the year 1883 the percentages were obtained which are graphically illustrated by the color shades on the annual map. They are divided into six grades of color, and show the proportion of cloudiness to range from over sixty per cent. of the time (one hundred being continuous cloudiness) to less than thirty per cent. The exact per cents. for each of the 136 signal stations are given in the tables, on the border of the map. It is interesting to note a somewhat intimate relation between increased cloudiness and increase of rain-fall and relative humidity, a fact which strengthens the belief that cloudiness is a good index of atmospheric humidity.

Temperature.—The average annual temperatures of belts of country stretching across the United States are represented by the *solid blue lines.* These *isothermal lines* are described by the figures (Fahrenheit scale) given at their termini on either coast. They are computed, according to the plan of the Signal Service, by dividing the sum of the 7 A. M., 3 and 11 P. M. observations by three to get each daily record. These isotherms represent the average of annual means for all time since the signal stations were established (for dates of establishment see annual tables), as do also the records given in the border tables for each station. The temperatures of places between isothermal lines can be approximately determined according to their nearness to the same.

Rain-fall.—The amount of rain and melted snow is accurately measured at each signal station (see Mean Precipitation in border tables), and the average yearly totals are graphically illustrated by the *interrupted blue lines* running over the face of the annual map. The inches of rain-fall are given at the termini of each of these lines on the border of the map. The variations in rain-fall within the boundaries of the United States are remarkable, being from less than five inches in southeastern California and southwestern Arizona to over seventy inches on the coast of North Carolina.

Winds.—An important part of the climatic maps to agriculturists, and to those who wish to prognosticate the state of the weather, is the record of the winds as to what winds bring pleasant weather and what usher in rain. Besides these two important facts, the prevailing direction serves to show whether pleasant-weather winds or rain-bearing winds are most likely to blow at any given place. All these three records are given by the *groups of arrows* which are scattered over the United States, the groups representing the regions in the center of or near which they are, and each kind of wind being indicated by a distinct form of arrow. These winds are the averages for the year 1882, and they blow as the arrows fly on the map, the quarter of the earth's surface, from which the pleasant-weather or rain-bearing winds come, being pretty nearly represented by the spread of the arrow's feather. *The velocity of the wind* at every signal station is constantly determined by a self-registering anemometer, and this valuable record (since the signal stations were established) is represented in the tables at the border of the annual map by the miles per month traveled by the wind. *The comparative windiness* is further given as determined by these records. For instance, Pike's Peak (1) is the windiest and La Mesilla (132) the least windy of all the places where the records are complete for the year, while the average for Denver, rating her as the 95th, shows that there are 94 out of 132 stations which are more windy than the "City of the Plains."

Elevations.—The elevations given in the border tables are the distances in feet, above sea-level, of the observation stations of the Signal Service Bureau, and are approximately accurate as representing the cities where these stations are. On the annual map the approximate elevation of sections of country are given which are over one thousand feet above the sea.

Ranges of Temperature.—Those who make a great point, as many do, of the precise variations of temperature, will be interested in the means of maximum and minimum and daily and monthly ranges of temperature, given in the border tables. The means of the maximum and minimum temperatures for 1883 are the averages of the daily highest and daily lowest temperatures for all the stations. From these two the mean daily range of temperature is computed, which is also given. The average or annual mean of monthly ranges of temperature is the average difference between the highest and lowest records in each month, and, with the daily range, indicates the equability or variability of a given climate. Many physicians, who had hitherto recommended equable climates for the classes of consumptives which can be benefited, have lately learned that *variability* is often to be preferred, as this quality pertains particularly to stimulating, dry, cool, and elevated climates, while *equability* always accompanies enervating warmth coupled with injurious dampness of atmosphere.

Relative and Absolute Humidities.—*Relative humidity* is the per cent. of moisture the air holds to what it would contain if it were saturated with vapor. It is always expressed in hundredths (saturation being 100), and the annual averages for all the signal stations are given in the border tables. A low average of relative humidity indicates the infrequency of fogs or dews as well as the presence of other qualities, as much sunshine and little rain, which produce a dry climate.

Absolute humidity is the real humidity of the air or the weight of vapor to a given space. It is usually reckoned in grains of vapor to the cubic foot of air. In the border tables of the annual map the annual record for 1883 is given in grains and hundredths, while in the tables of the seasonal charts it is given in tenths of a grain of vapor to a cubic foot of air.

Dew Point.—This is the temperature at which the air will become more than saturated by the amount of vapor it contains. The annual mean dew point, which is that given in the border tables, is always lower than the given mean

temperature of a place. The reason is this: the air can hold moisture according to its temperature, the range being very great—*i. e.*, from about one half a grain to the cubic foot of air at zero to over nineteen grains at 100° F. Now, the annual average of relative humidity never exceeds 90 per cent., so the temperature must be lowered for dew to be deposited. The explanation is similar considered with reference to absolute humidity. A place which has four grains of vapor to the cubic foot of air and a temperature of 62° (66 per cent.) must have its temperature reduced to 49° when four grains will just exceed saturation. The greater the difference between the mean dew point and mean temperature of a place, the less frequently do fogs occur.

Vapor Tension.—This is the elastic force of vapor, and represents the expansibility of the vapor of water the air contains. The moister the air, the greater is its elasticity or pressure. This elasticity is determined by the difference between the wet- and dry-bulb thermometers, and is expressed in hundredths of English inches (see border table for annual means). This method of expression is used because the expansibility of the air, due to the vapor it contains, is determined by the depression in inches of a column of mercury when acted on by this force.

II. The Seasonal Charts.—The seasonal charts serve a special purpose in presenting all important climatic data in quarterly divisions, which method has many advantages over the annual representation. In the annual statistics we have not even approximate representations of either summer or winter, for, being on opposite sides of the mean for spring and autumn, they neutralize each other when combined, and the significance of each is lost. The seasonal division of the year is therefore necessary in order to show the contrasts between winter and summer. It aids the mind in retaining correct impressions of separate data, while a semi-annual subdivision would be rather impracticable, and monthly statements too confusing to be remembered. The study of climate by seasons is the most satisfactory and the most rational method for physicians, agriculturists, health seekers, tourists—in fact, the great majority of those interested in climate.

Combined Humidities.—An important and peculiar object of these seasonal charts is to illustrate a classification of climates which the author has originated after much deliberation. It is that which is given in the blue and red color shades, and is based upon an equitable combination of the humidity statistics of the atmosphere for 1883. The object being to rate all sections according to their records, nearly a third the rating influence is given to each of three attributes of climate, namely, *cloudiness* and *relative humidity* per cent., and *absolute humidity* in tenths of a grain of vapor to the cubic foot of air; or, perhaps, more definitely, about 35 per cent. to the first, 40 to the second, and 25 per cent. to the third, in the order named. The object of this rating is to correct the mistake of judging by any one evidence of moisture or dryness. Cloudiness is uninfluenced by the faults of temperature or absolute humidity records taken in cities, and is comparatively independent of purely local effects; yet cloudiness is somewhat of a relative quantity, since the upper strata of the atmosphere must reach saturation in order that clouds may exist. Relative humidity would be an admirable test of atmospheric humidity were it not so fickle and under the dominion of faulty temperatures and changing winds. Absolute humidity, however, is more stable. It is an actual, *real* statement of the amount of atmospheric moisture, and serves as an excellent means of correction for relative humidity. For instance, Pike's Peak for spring, with a high relative humidity of ·84, has a low absolute humidity of nine tenths of a grain of vapor because of its low temperature, 15°; while Cedar Keys, with a less relative humidity, ·73, has a high absolute humidity—five and seven tenths grains—because of its high average temperature, 70°, for the same season. So each of these factors corrects the faults of the other two, and all of them combined better represent the climate of the country than any one of them alone can do. The finally accepted method of combining these statistics was to rate every station, forward or backward, from the average, which was assumed as the middle of climate for the United States. This mean of humidity statistics for the year would be represented by the average of the dividing lines between the blue and the red shades on the four charts. It is this yearly average with which all places are compared, those of more moisture being thrown appropriately into the shades of moisture (blue), and those opposite into shades of dryness (red). Since absolute as well as relative humidity is dependent on temperature, the capacity of the air to hold moisture varying according to temperature, it became necessary to have a separate rating standard or figure for each degree of temperature. Thus the "Rating Table" and the "Rule of Moisture and Dryness" were constructed, which are given both on the summer seasonal chart and on the annual map. The rating figures represent one third the sum of the three rating factors, and with this a third of the records of every place is compared. It must be remembered that this is not a geographical mean; so it is not essential to accuracy that the moist half should exactly correspond in area to the dry half. To get a fair mean as the basis of the "Rating Table," the averages of the separate factors were determined according to methods of computation approved by those in authority to judge of this subject. These means were found to be 44½ per cent. for cloudiness, 67 per cent. for relative humidity, and 67 per cent. of saturation for absolute humidity, expressed in tenths of a grain of vapor to the cubic foot of air. By these standards combined the proper climatic rating of every locality is determined, based upon the official and unbiased records of the Signal-Service Bureau. Thus a much-needed definition is obtained of what *moisture* and *dryness* mean as applied to climates. The moist and dry halves are each divided into four equal divisions, which are respectively represented by the blue and red shades on the seasonal charts. The seasonal peculiarities of localities and the relation of seasons to each other are thus well illustrated. Instance the large area (see winter chart) in the Northwest and in the Northern Lake and Central River regions, which are thrown into the solid blue shade of the extreme of moisture by the cold of winter, and the equally

large area (see summer chart) in the Southwest that is thrown into the solid red shade of the extreme of dryness by the heat of summer. Thus the laws which govern the diffusion of heat and terrestrial radiation are at many points illustrated by these charts. It is hoped this seasonal presentation of combined humidities will be appreciated, especially by those who would avoid undesirable weather in one season by a temporary removal to a more genial clime.

(*To be concluded.*)

THE PRINCIPLES INVOLVED IN THE CONSTRUCTION OF SPRAY-TUBES.*

By ANDREW H. SMITH, M. D.

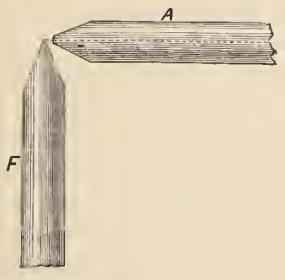
The Bergsen, or, as it is more commonly called in this country, the Sass spray-tube, having practically superseded all other forms, it is to this that attention will be confined in this paper.

The instrument consists essentially of two tubes placed one above the other, the upper one, which for brevity's sake we will designate A, carrying compressed air or steam, while the lower one, which we will call F, supplies the fluid to be atomized.

The free extremities of these tubes, greatly diminished in size, are so arranged in relation to each other that the stream of air issuing from A passes at a right angle across the tip of F. The action of the spray-tube depends upon the fact that air possesses a considerable degree of adhesiveness, the different particles adhering to each other with no little tenacity.

We are familiar with this property in viscid fluids and to a less degree in plain water, a drop of which can be drawn along a table by the finger, but we are not apt to think of it as belonging to the atmosphere or to gaseous bodies. Yet it is owing to the fact that the air or steam which escapes from A clings to and drags with it the air at the extremity of F that a vacuum is produced in F. Into this vacuum the fluid rises, and in its turn is caught by the current from A and dispersed in the form of spray.

The greater the velocity of the air-jet escaping from A, the greater will be the exhausting force exerted upon F, and therefore the greater the efficiency of the atomizer. As the velocity of the stream of air is greatest at its center,



where it is least retarded by friction, it follows that the axis of the opening of A should be exactly on a line with the extremity of F.

The pressure being the same, the character of the spray will depend upon the relative size of the openings of A and F. Increasing the former permits more air to escape and gives a larger volume of spray with a greater carrying force and more power of penetration. Increasing the latter results in a larger consumption of fluid, forming a coarser spray, and, if carried too far, results in dripping.

A large opening for A with a small one for F gives a large body of very fine spray. A small opening for A with a large one for F gives a small body of coarse spray. A successful application of spray to the throat or to the posterior nares often requires that it be effected as it were by surprise, and before there is time for reflex action of the muscles. Hence it is necessary that spray should be formed the instant the air-valve is opened; for, if the arrival of the liquid at the point of F is delayed appreciably after air begins to issue from A, reflex contraction will have been excited by the contact of the air with the mucous surface before any spray is produced. Now, no fluid will reach the point of F until all the air in F is exhausted, and the amount of air and the length of time required for its exhaustion will be in proportion to the length and the caliber of the tube. Hence these should be reduced to a minimum in spray-tubes intended for making quick applications. And, as there is nothing lost in any case by this construction, it may as well be made the general rule for all tubes.

With a properly constructed spray-tube comparatively slight air-pressure will suffice for all purposes. Increase of pressure will compensate in a measure for defective construction of tubes, but it brings with it its own inconveniences, such as mechanical irritation of the surface to which the spray is applied, waste of compressing power, etc.

The indications for the use of coarse or fine spray do not come within the scope of this paper, and will vary in accordance with the views of individual practitioners.

* Read before the American Laryngological Association, June 25, 1885.

ALCOHOL IN THE TREATMENT OF ACUTE AND CHRONIC FORMS OF ALCOHOLIC MANIA.

By LEWIS D. MASON, M. D.,
CONSULTING PHYSICIAN TO THE INEBRIATE HOME, FORT HAMILTON, N. Y.

While in certain forms of neuroses, occurring in cases of alcoholism, alcohol in any form would be injurious, nevertheless there are conditions in which the judicious use of alcohol is not only beneficial, but curative and indispensable, and its place can not be taken by other drugs. The assertion that alcohol is only and always a poison, and must not be tolerated in any condition, especially where the inebriate is concerned, is not carried out by our experience in the class of cases to which we shall presently refer. The indiscriminate and therefore injudicious and harmful use of alcohol is not here indorsed; we now speak of its careful administration, where the quantity and form used are regulated by a competent practitioner. An asylum experience of over nineteen years, embracing the cases of several thousand inebriates, has given us ample opportunity to test the relative value of sudden and complete abstinence from all alcohol, and the plan of gradual reduction, or what is known

as the "tapering-off" system. And just here it is legitimate to reason from analogy. Our experience has also embraced many cases of the opium and morphine habits. In a few of the earlier of this class of cases under our treatment the drug was left off abruptly. The terrible suffering and collapse that ensued demanded the immediate restoration of his full dose to recover the patient from a state of suffering, if not peril, and the endeavor by some other and less severe method to relieve him of the habit.

The same holds true in degree in certain cases in regard to alcohol. The inebriate, whose nervous system is broken down by his excesses, is suddenly deprived of his accustomed stimulant. Some hours may pass and nothing worthy of note happen; but in time the symptoms of deprivation manifest themselves, and he pleads for his usual draught, and will resort to all kinds of deceit or force to obtain it. He fails by reason of his environments, and then mental aberration, muscular tremor, insomnia, and the familiar symptoms of delirium tremens are established. This is the common experience of the hospital surgeon. The habitual inebriate, struck down by some accident, is brought into the hospital ward. He is thus suddenly deprived of all stimulants, and the necessity for administering the same is not recognized. A few hours pass, sleeplessness ensues, and a case of delirium tremens, associated with surgical injury, is established. And the hospital surgeon could not meet with a worse complication, especially in certain forms of injury, such as fracture, where perfect rest is so essential to secure proper results.

During the first few years of our experience at the Inebriate Home at Fort Hamilton the "cut-off plan" from all alcoholic stimulants was conscientiously adopted. Recognizing the great evil that alcohol had done, we did not desire to place it on record as of any use at all; and, further, the popular cry that inebriate asylums "were nothing more than hotels for the accommodation of a certain class who desired to continue their evil habits" influenced us somewhat to adopt this plan.

Cases of delirium tremens were common. Hardly a person entered the asylum but he was expected to pass through his attacks of acute delirium. At present this is an exception to the rule. If a patient enters the asylum, and is at all tremulous, especially if he has had a long, tiresome journey, and the experience of a sleepless night and deprivation from his accustomed stimulant, he is regarded as on the verge of an attack of delirium tremens, and the judicious administration of a few bottles of ale, or its equivalent in some other form of alcohol, given at proper intervals, will not only quiet him, but tone up his nervous energy and arrest a condition rapidly tending to delirium.

Many enter who do not need such treatment. The periodic dipsomaniac who is on the tail-end of his spree and is ready, after a day or two of rest, to again enter upon his sober interval, will probably not need such stimulant. The person most likely to demand it is the habitual inebriate, because, of the two, the nervous system of the latter is the most shattered, and because, also, he is accustomed to a daily stimulant. It must not be inferred that, in our asylum, alcohol is improperly, indiscriminately, or irregularly given. On the contrary, it is dispensed with as much care and caution as other drugs. A record of the quantities given, and the periods at which they are administered, in each case is kept, as well as the effect upon the pulse, temperature, and general condition of the patient. As a prophylactic or abortive treatment for delirium tremens, I know no remedy so safe and so potent as alcohol properly administered. I believe that insomnia is more readily overcome, and the end desired more promptly attained, than if we attempted to secure the same result by large doses of the bromides, chloral hydrate, or other hypnotics, and the risk that attends the use of these drugs avoided. If we have occasion to use these drugs also, less will be necessary, so that the quantities used may be administered in safer doses. I do not hesitate to assert that, by the too free use of these drugs in cases of delirium tremens, in the effort to overcome the persistent insomnia, the convalescence of the patient has been greatly retarded, and life has been put in jeopardy and even sacrificed.

The method, then, of administering alcohol should be regulated by the condition of the patient. On the first appearance of sleeplessness, mental aberration, muscular tremor (and these should be watched for in all cases submitted to our care), a bottle of Bass's ale may be given every two, three, or four hours, lengthening or shortening the interval as the case demands, and then, after sleep is obtained and the patient reacts from his mental irrationality and physical depression, the use of the stimulant be suspended.

The use of a stimulant may be necessary for a day or so, or longer periods. We find it rarely necessary to continue it longer than a week or ten days, gradually decreasing the quantity, and at the end of that time total abstinence may be safely practiced for an indefinite period. I have seen several instances, both in private and asylum practice, where the judicious use of ale alone, without other medication, has arrested in a few doses the tendency of the patient to acute delirium, and restored him to a safe condition of sleep and mental soundness. And, even in cases where the delirium was marked and the insomnia persistent, the judicious use of stimulants has put the patient on the road to recovery. Ale will often succeed where whisky or other forms of alcohol do not answer. After a night or two of rest, the mental and physical condition of the patient meanwhile improving, we may begin reduction and carry it on as speedily as the case seems to warrant, and in a few days the patient will be convalescent. If the case is one accompanied by severe injury, it may be well to continue the stimulant until the period of debility or shock has passed, or the exhausting drain on the system has been arrested.

In chronic alcoholic dementia—a low type of mental alienation occurring in alcoholics—the patient is anæmic, listless, and full of delusions; hears voices, and holds conversation with imaginary persons; appears to have sane moments, but readily relapses into his old delusions; his appetite is capricious, his sleep irregular, and his physical strength poor; he moves about in a waking nightmare, he walks in a land of dreams and shadows. The judicious use of stimulants in these cases, a glass of ale at each meal and at bed-time, conjoined with tonic treatment, proper diet, and regular exer-

cise, will do much good. The use of bromides and chloral to overcome the insomnia will only add to the already profound mental disturbance and still further lower the physical tone. I have already referred to the fact that the too free use of the bromides and chloral and other depressing drugs in the acute forms of alcoholic delirium may plunge the patient into the more protracted forms of mental alienation to which the inebriate is particularly prone. I have endeavored to be cautious in presenting my views; but our experience at the Fort Hamilton Asylum will not permit me to indorse the idea held by some practitioners—viz., that no harm can result from leaving off at once alcoholic stimulants in any case, and that no good can result from continuing them in any case of alcoholism; that their use is not only productive of mischief to the patient, but is, besides, a great shock to the moral sense of the community. I maintain, however, that, if, by the judicious use of alcohol in such quantities and at such times as we may direct, we can arrest the onset of an attack of alcoholic delirium, or abbreviate the duration of the more chronic forms, the result of the treatment certainly warrants its adoption. In order that my statements need not be misapplied or misconstrued, it may be necessary to state that there are many persons who drink alcohol in some form habitually, but never to excess or intoxication, and who have not passed through the terrible ordeal of delirium tremens, chronic alcoholism, or chronic alcoholic mania, and who have not yet been convulsed with alcoholic epilepsy. To such my remarks do not apply. These persons are not inebriates in the true sense of the word. Immediate and abrupt cessation with them means nothing more than the leaving off of a very pernicious habit, which, if continued, will carry them into the terrible precincts of the inebriate. All such I most earnestly advise to leave off alcohol at once. Total and immediate abstinence is their only safety.

Nor do we hold that all patients entering the Inebriate Asylum demand the treatment herein indicated. But I wish to impress the fact that a certain class of cases require alcohol in some form as a part of their treatment, and that in these cases it is especially indicated. We all recognize the moral side of the question; but, when a life is wavering in the balance, we must use the means which experience has proved to be the best.

One of the best and most conservative authorities in this special department of medicine indorses the judicious use of alcohol, if not directly, at least indirectly, and comes somewhat to our aid on this point. Speaking of digitalis and its effects in large doses in the treatment of delirium tremens—doses of half an ounce or an ounce of tincture of digitalis—he writes: "The patient must have received so much proof spirit;" and he is puzzled to account whether it was the alcohol or digitalis that effected the good result, and, although opposed to alcohol, says the favorable issue was either due, probably, in the large number of successful cases, to a spontaneous favorable termination of the disease, or was slightly helped by the alcohol which is contained in the tincture ordinarily employed. The "cut-off" plan is also considered by the writer; but he says it is more difficult to carry out this plan with older patients . . . accustomed to depend for a long time on strong drink as a large part of their nutrition. "But still," he writes, "we ought to try less harmful drugs—opium, Indian hemp, etc.—before resorting to so doubtful a remedy as alcohol." Again: "Alcohol, also, in diminishing doses, does seem to aid in the cure of feebler cases. If a man has been drinking a quart of whisky daily up to the time of his attack, a pint or quart of ale or porter will be to him only a mild tonic beverage, aiding his digestion." And, finally, the author is forced to this admission: "The popular idea of tapering off is not altogether devoid of scientific, as well as clinical, foundations." *

Another point to note, and of some value in gaining the confidence and sustaining the courage of the patient in the ordeal that he is to pass through, is the fact that his stimulant will not be immediately "cut off" if it is necessary to administer it.

I have no donbt that many persons desirous of entering a special asylum for the treatment of their diseased appetites would do so if they did not dread the sudden deprivation from their accustomed stimulant. When a patient is brought to our asylum, his first and only question often is, "Will they cut me off at once?" This thought is uppermost in his mind, intensifies his desire, and aggravates his nervous apprehensions.

If we can, by the judicious use of a stimulant, carry him over the first few days of his asylum experience, quiet his fears, secure to him rest, and gain his confidence, we have brought him successfully over the first part of his treatment, and, in all probability, arrested a train of nervous phenomena that would, if allowed to go unchecked, have precipitated him into an attack of acute delirium, or permitted him to drift into the more chronic form of alcoholic mania.

TWO CASES OF CROUP
TREATED BY
TUBAGE OF THE GLOTTIS.

By JOSEPH O'DWYER, M. D.

A BRIEF account of my experiments in the treatment of croup by tubage of the glottis, with illustrations of the tubes and other instruments used, was published in the "New York Medical Journal" of August 8th last. I have since devised a much better extracting instrument than any previously tried, and also made some slight modifications in the tubes.

Since preparing the article above referred to, I have treated two cases of croup, both of which occurred in the service of Dr. C. C. Lee at the New York Foundling Asylum. They were carefully observed and complete records kept by Dr. Dillon Brown, the house physician:

The first case was that of Albert L., aged three years and three months, who had a rather mild attack of diphtheria beginning on July 9th, which was unattended by very serious symptoms until the night of the 12th, when the voice became husky and the characteristic croupy cough began. During the following day there was a moderate amount of dyspnœa, which

* Dr. Francis Edmond Anstie (Reynolds's "System of Medicine").

increased during the night and became severe early on the morning of the 14th.

Emetics, inhalation of steam, and hot poultices to the throat gave only temporary relief. When I was called, at 3.30 P. M., the dyspnœa was so extreme that I introduced a tube immediately, and without difficulty, the time occupied by the operation, after the gag had been inserted, not exceeding ten seconds. It gave rise to a vigorous spell of coughing which lasted at intervals for about half an hour, during which a considerable quantity of muco-purulent secretion was expectorated. After a quiet and very natural sleep, lasting almost two hours, he drank half a goblet of milk with a teaspoonful of brandy, which was swallowed with very little difficulty. Temperature in the axilla 101·9°, pulse 140, respiration 30.

15th.—Slept almost continuously during the night, looks well, and is quite cheerful. Asks for drink in a faint whisper. Some bronchial râles over the chest posteriorly. No membrane visible in the pharynx. Temperature 99·3°, pulse 144, respiration 30.

16th.—Passed the night very comfortably. Suffers greatly from thirst, owing to the extreme heat of the weather. Vomited several times during the day in consequence of having taken too much milk. Ordered cracked ice and iced Vichy, to allay thirst, and milk to be limited to three pints in the twenty-four hours.

18th.—Passed the two preceding nights very comfortably, sleeping most of the time. Coughs very little, except when drinking. Temperature 100·9°, pulse 160, respiration 35. The afternoon temperature, taken for the first time in the rectum, was found to be 103·5°. Removed the tube at 3P. M., ninety-six hours from the time it was inserted. For a short time the breathing remained perfectly free, and the cough, which increased when the tube was removed, for a while retained its tubal character, but soon became croupy again, and the obstruction returned so rapidly that I was obliged to reinsert it at 4.30. Has passed only about one ounce of urine in the last twenty-four hours, which contained a considerable amount of albumin and blood-corpuscles, but no casts. Given infus. digitalis with acetate of potassium, and hot poultices applied over the kidneys.

19th.—Spent a very restless night. Vomited and had several loose passages. Temperature 102·9°, pulse 168, respiration 42. Nothing found on auscultation but bronchial râles.

20th.—Passed a more comfortable night. Urine increasing in quantity; vomits occasionally. Temperature 102°, pulse 156, respiration 40. Removed the tube at 2·30 P. M., and was obliged to replace it at 4 P. M.

21st.—Slept almost the whole night. Excessive thirst continues. Temperature 101·9°, pulse 144, respiration 24. Sat up several hours and was quite playful.

22d.—Removed the tube for the third time at 2.45 P. M., and had to replace it in an hour and a half. Temperature 103°, pulse 156, respiration 36.

23d.—Temperature 102°, pulse 132, respiration 36.

24th.—Tube removed at 11 A. M. and reinserted at 11 P. M. Temperature 101°, pulse 138, respiration 30.

25th.—Removed the tube for the fifth time. Cough soon became croupy, but without any marked dyspnœa during the day.

26th.—Did not sleep so well as usual. Some dyspnœa. Temperature 103°, pulse 160, respiration 42.

A careful examination of the chest revealed nothing but bronchial râles. Although the dyspnœa was not marked, the tube was reinserted, with immediate improvement in all the symptoms. The pulse fell to 130 and the respirations to 26. The tube was finally removed on the 28th. The cough continued croupy with some elevation of temperature for several days subsequently, but convalescence was uninterrupted. Urine found free from albumin, August 4th, for the first time. He was sent out to board soon after, and I did not see him again until October 30th, when his voice was perfectly restored. I learned from his foster-mother that complete aphonia persisted for about four weeks after his removal from the asylum.

The tube used in this case was two inches and an eighth in length, and of much smaller caliber than the tracheal cannula in common use. It is quite probable that the long continuance of the obstruction—fourteen days (the longest time in any previous case being ten days)—was due in some degree to œdema of the tissues of the larynx, superinduced by the nephritis.

The second case was that of John E , aged sixteen months, always a pale, delicate child, who had a severe attack of diphtheria, beginning on October 10th. There was extensive pseudo-membranous deposit in the pharynx, with marked swelling of the tonsils and severe constitutional disturbance. The first symptoms of croup appeared on the 13th, and I was called at 2 P. M. the following day. The breathing was then very much obstructed and noisy, with marked recession of the sternum and lower ribs during inspiration, but no restlessness nor other evidence of suffering. The swollen tonsils, still partially covered with membrane, had an excavated, sloughy appearance, and the surface of the body was extremely pale; even the lips had no color. Temperature 102°, pulse 198, respiration 28.

As the case was absolutely hopeless, I concluded to resort to tubage only in case of severe suffering. I was called again at 5 P. M., and found him extremely restless and evidently suffering very acutely. I inserted a tube one inch and three quarters long with some difficulty, as there were no double teeth to hold the gag, and it was difficult to keep the mouth well open. The relief to the dyspnœa was complete, the pulse soon fell to 160, and his general condition was for a time considerably improved. He took milk and brandy in sufficient quantity, but did not swallow so well as the preceding patient.

15th.—Passed the night in a fairly comfortable manner. Early in the morning the temperature was 104·5°, pulse 192, respiration 54; 2 P. M., respiration 70, pulse and temperature about the same. Bronchial râles, of all kinds and in great profusion, heard everywhere over the chest, while the resonance was not impaired. Death took place, without much apparent suffering, at 5 P. M., twenty-four hours after the tube was inserted.

At the autopsy, six hours after death, the lungs, which receded normally when the chest was opened, were found perfectly normal, there being neither emphysema, atelectasis, nor even an abnormal amount of blood in them. A thick deposit of pseudo-membrane was found in the larynx, trachea, and bronchial tubes, as far as the third or fourth division, the caliber of the right and left bronchus particularly being reduced to a very small size. The tube, which was perfectly clear, reached within about half an inch of the bifurcation. The right heart contained a well-washed clot.

In the majority of the fatal cases of this disease, after obstruction in the upper air-passages has been overcome, it is difficult to exclude incipient pneumonia, owing to the presence of more or less congestion and atelectasis; but in such cases as the one just recorded, and I have notes of several similar cases, the high temperature and accelerated breathing, in the absence of anything else to account for them, must be attributed to the extension of the diphtheritic process into the bronchial tubes.

Dr. Waxham, of Chicago, who procured a set of my tubes early in the present year, recently reported five cases of croup treated by this method. Dr. Brush, of Mount Vernon, has also used them in two cases.

858 Lexington Avenue.

Book Notices.

Doctrines of the Circulation. A History of Physiological Opinion and Discovery in regard to the Circulation of the Blood. By J. C. Dalton, M. D., Professor Emeritus of Physiology in the College of Physicians and Surgeons, New York, and President of the College. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. 296.

This little work, as its title suggests, is largely historical. Beginning with Aristotle, the idea of the circulation is traced step by step to the school of Alexandria, through the period of the Renaissance to the age of Fabricius, and finally to the time of Harvey.

Although an unassuming book, it shows evidences of a vast amount of research. Many curious and interesting facts are introduced from the works of the older writers, and in an appendix (including upward of fifty pages) there are numerous Greek and Latin citations. The book is a valuable one, not only to the special student and lover of the quaint and curious, but to the general medical reader.

Lectures on Phthisis Pulmonalis. Delivered at the Detroit Medical College, Detroit. By Ernest L. Shurly, M. D., Professor of Laryngology and Clinical Medicine, Detroit Medical College, President of the American Laryngological Association, etc. Detroit: George S. Davis, 1885.

In this little volume of about a hundred pages Professor Shurly has given, with admirable clearness and brevity, an instructive *résumé* of our present knowledge of the subject of pulmonary phthisis. To this he has added the results of a wide, intelligent, and carefully digested personal experience. The treatment of phthisis and its complications is considered with great thoroughness, and this department, occupying as it does about one half of the book, will be read with unusual interest and profit.

A Practical Treatise on Fractures and Dislocations. By Frank Hastings Hamilton, A. B., A. M., M. D., LL. D., Late Professor of Surgery in Bellevue Hospital Medical College, and Surgeon to Bellevue Hospital, etc. Seventh American Edition, Revised and Improved. Illustrated with three hundred and seventy-nine woodcuts. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxxi–1005.

It is unnecessary to repeat the words of commendation which have so often been used with reference to this work, which has now become classical. The present edition is fully up to date, the alterations and additions being suggested, as the author says, by recent journal articles. He acknowledges his indebtedness for new material to Dr. Stimson, of New York, and Dr. Poinsot, of Paris. The treatise is eminently practical; indeed, it is the author's purpose throughout to avoid empty theories, and to introduce only such facts as have stood the test of clinical experience. It is with no small feeling of pride that an American points to "Hamilton on Fractures and Dislocations" when the originality of his countrymen is called in question. Such works as this, embodying the results of the practice of several generations of medical men, redeem us from the charge of superficial work, and prove that, whatever may be the failings in our system of medical education, practical ingenuity and common sense are not wanting with us.

BOOKS AND PAMPHLETS RECEIVED.

The Pedigree of Disease: being Six Lectures on Temperament, Idiosyncrasy, and Diathesis, delivered in the Theatre of the Royal College of Surgeons, in the Session of 1881. By Jonathan Hutchinson, F. R. S., late Professor of Surgery and Pathology in the College, etc. New York: William Wood & Co., 1885. Pp. 113.

A Text-Book of Nursing, for the Use of Training-Schools, Families, and Private Students. Compiled by Clara S. Weeks, Graduate of the New York Hospital Training-School, etc. New York: D. Appleton & Co., 1885. Pp. 396. [Price, $1.75.]

Manual of the Diseases of Women, being a Concise and Systematic Exposition of the Theory and Practice of Gynæcology, for Use of Students and Practitioners. By Charles H. May, M. D., late House Physician, Mt. Sinai Hospital, New York, etc. Philadelphia: Lea Brothers & Co., 1885. Pp. xi–25 to 357, inclusive.

Official Formulæ of American Hospitals. Collected and Arranged by C. F. Taylor, M. D., Editor of the "Medical World." Philadelphia: The "Medical World," 1885. Pp. 238. [Price, $1.]

Diseases of the Larynx. By Dr. J. Gottstein, Lecturer at the University of Breslau. Translated and Added to by P. M'Bride, M. D., F. R. C. P. E., F. R. S. E., etc. Edinburgh and London: W. & A. K. Johnston. Pp. 274.

Post-mortem Examinations, with Especial Reference to Medico-legal Practice. By Professor Rudolph Virchow, of the Berlin Charité Hospital. Translated by T. P. Smith, M. D., M. R. C. S. E., with Additional Notes and New Plates. From the Fourth German Edition. Philadelphia: P. Blakiston, Son, & Co., 1885. Pp. 138. [Price, $1.]

On the Tests for Muscular Asthenopia, and on Insufficiency of the External Recti Muscles. By Dr. Henry D. Noyes, of New York. [Reprinted from the "Transactions of the Eighth Session of the International Medical Congress."]

Tracts on Massage. No. II. The Physiological Effects of Massage. Translated from the German of Reibmayr, with Notes, by Benjamin Lee, A. M., M. D., Ph. D., etc. Philadelphia, 1885. Pp. 46.

The Therapeutics of High Temperatures in Young Children. By William Perry Watson, A. M., M. D., Jersey City, N. J. [Reprinted from the "Archives of Pædiatrics."]

Observations on the Cause and Treatment of Infantile Eczema and Allied Eruptions. By Henry T. Byford, M. D., Chicago. [Reprinted from the "Journal of the American Medical Association."]

Letters from a Mother to a Mother on the Formation, Growth, and Care of the Teeth. By the Wife of a Dentist, Mrs. M. W. J. Philadelphia: Welch Dental Company, 1885. Pp. 106. [Price, 25 cents.]

Report on Ophthalmology. By A. M. Wilder, M. D., etc. [Reprinted from the "Transactions of the Medical Society of the State of California."]

The Causal Relation of Obstructed Cardiac Circulation to Lymph Stasis. By Samuel C. Busey, M. D., Washington. [Reprinted from the "American Journal of the Medical Sciences."]

Primary Lateral Spinal Sclerosis. By J. B. Marvin, M. D., etc. Read before the Kentucky State Medical Society, June 26, 1885.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, NOVEMBER 28, 1885.

WHAT MAY COME OF A SUIT FOR DAMAGES.

Our readers need not be told—for those of them who have long followed the practice of medicine are painfully aware of the fact—that medical men are peculiarly subject to injustice at the hands of the law. As one of our English contemporaries has lately remarked, the very institution that ought to be an unfailing and readily available refuge for any man who is conscious of his rectitude—the law—is becoming more and more a remedy worse than the disease, if not an engine of oppression. "He who filches from me my good name steals that which not enriches him, but makes me poor indeed," may many a man of our craft exclaim when he finds himself in its toils. Whether he has been goaded to seek redress in the law, or has been made against his will to take a position that subjects him to the gibes of every loafer who reads the vulgar newspaper accounts of things medical, he is lucky if on any such occasion he can look back on the affair, after all is over, with more satisfaction than regret.

If this can be said of the legal entanglements to which physicians are ordinarily and everywhere liable, what will be thought of a state of things in which obedience to the law is the very act that leads to punishment? This is what seems to have been exemplified recently in New York? One of the ordinances of the sanitary code makes it incumbent on physicians to notify the Health Department of cases of infectious disease, and they are subject to a heavy fine for any neglect to do so. Several years ago Dr. A. E. M. Purdy, an esteemed practitioner, gave notice to the Health Department, under this regulation, that, in his opinion, a young woman who was under his treatment was suffering with small-pox. Thereupon the Department sent one of its medical officers to visit the patient, and it appears that he agreed with Dr. Purdy as to the nature of the case, and the woman was removed, contrary to her will, to a public hospital set apart for infectious diseases. Her sickness proved to be of short duration, and she was not long detained, but she has now brought suit against Dr. Purdy for damages, alleging that the business in which she was engaged has been seriously injured by the fact that her old customers, having learned of her misfortune, shunned her shop; and, further, that Dr. Purdy's diagnosis was erroneous, since she did not have small-pox, but simply a dermatitis of the face, caused by a preparation containing acetic acid having accidentally come in contact with it. She sued for ten thousand dollars damages, and last week a jury awarded her five hundred dollars.

We can scarcely regard this verdict in any other light than as a miscarriage of justice. In the first place, Dr. Purdy still maintains the correctness of his diagnosis. It is in evidence that the sanitary inspector agreed with him, and he certainly seems to us to have been entitled to any doubt that might arise in the attempt to establish a retrospective diagnosis. It is to be borne in mind, too, that Dr. Purdy is a gentleman of mature experience, familiar with the clinical picture of small-pox and fully alive to the considerations that always restrain prudent men from condemning patients to the odium and discomfort involved in public information of their having such a disease, until they can no longer avoid that course. *A priori*, then, the assumption that the diagnosis of small-pox in this case was incorrect would seem to rest upon a very slim foundation.

But, allowing that it was incorrect, it is difficult to see the equity of holding the physician responsible for the misfortunes that happened to the patient in consequence of that diagnosis having become known. The notification to the Health Department was merely the expression of an opinion on the part of a man whom the law compelled to express his opinion. The Health Department did not rest satisfied with that opinion, but sent one of its own inspectors to examine into the facts. The information upon which the patient's removal from her home was decided on came, therefore, not from the physician in attendance, but from the Department's own officer. The straightforward interpretation of these facts would seem to relieve Dr. Purdy of all responsibility in the case.

We have heard it said that Dr. Purdy was sued in this case because a suit could not be brought against the Health Department. If the Department is really hedged about by such a divinity, it seems to us that the sooner it is removed the better. It is notorious that heretofore the reports of infectious diseases to the Board of Health have been exceedingly defective; what will they be henceforth, since it is virtually proclaimed that whoever reports a case does so at his peril? The Board has been lenient in inflicting penalties, so lenient as recently to have called forth severe criticism from a well-known citizen, and we lately took the trouble to offer certain excuses in its behalf. In the light of the verdict in the Purdy case, we doubt if any amount of leniency on the part of the Board, in so far at least as concerns reports of cases of infectious disease, will not be countenanced and even insisted on by the community. Should the case become a precedent, our registration of infectious diseases will practically cease to be founded on anything else than such cases as the sanitary inspectors may stumble upon, for our medical practitioners will surely choose to risk having to pay a specified sum, however onerous it may be, rather than incur the danger of being mulcted still more heavily. Small-pox will then be "given a fair chance," and everything will be lovely.

THE COUNTY SOCIETY AND THE CASE.

An extraordinary piece of business came before the Medical Society of the County of New York at the meeting held last Monday evening, being none other than the consideration of the suit in which Dr. Purdy was lately the defendant, and in which the jury brought in a verdict of damages in five hundred dollars against him. The main features of the case were those that we have set forth in the preceding article.

Associations for the legal defense of medical men are not unknown abroad, and, in the absence of any such organization in this community, we know of no good reason why the county society should not on occasion assume such a rôle. We are glad, however, that the meeting was prudent enough not to engage in a discussion of the way in which the further conduct of Dr. Purdy's defense should be carried on, in case of appeal, but contented itself with empowering the Comitia Minora to take such action in the matter as it might deem best.

We trust that the Comitia will act more carefully about the affair itself than it seems to have acted in preparing what was probably meant to be a notification that this particular business would come before the meeting. "Shall the medical profession," says the notice, "be subjected to a penalty of five hundred dollars for reporting contagious diseases to the Health Department of this city?" We hope that we shall hear of no more instances of individuals being mulcted on such grounds, and we are quite confident that "the medical profession" will not be so mulcted; and, if damages are again awarded in such a case, we do not know that it will necessarily be in the sum of five hundred dollars. But the Comitia "means well."

MINOR PARAGRAPHS.

THE REPORT OF THE SURGEON-GENERAL OF THE NAVY.

The report for the year ending September 30, 1885, is not a long document, for it makes only a pamphlet of seven pages. It states that the appropriations for the repairs of hospitals have been so small that the Bureau has not been able to maintain those institutions in a satisfactory condition, and that the further reduction for the current year may cause serious embarrassment. The Surgeon-General is, therefore, compelled to ask for an increased appropriation for the coming year, in order to maintain the establishments in the necessary state of preservation. He calls attention anew to the bad condition of the drains of the hospital inclosure at Portsmouth, N. H. The quarantine temporary hospital lately built on Widow's Island, in Penobscot Bay, has been inspected by the Surgeon-General, and he reports that its construction is satisfactory, and that he saw no evidences of any feeling of anxiety among the residents of Rockland or North Haven about the risks of disease being introduced from ships that might visit the station. He considers it a safe and desirable refuge for infected vessels from the West Indies or the Gulf of Mexico. One hundred and seventy-eight articles have been added to the Museum of Hygiene, and eight hundred and thirty books to the library.

MORE NEWSPAPER MEDICINE.

One of the daily newspapers lately published a long dispatch from Cleveland, O., setting forth the wonderful features of a case of triple gestation, in which one of the children was born several days after the two others, and of a case of dermoid cyst. There is usually a lurking suspicion that the physicians in attendance are in some measure answerable for newspaper articles of this type, but we are quite ready to absolve the accoucheur from the charge of having connived at the publication of such a state of things as happened in the first case.

NEWS ITEMS, ETC.

The New Jersey Sanitary Association held its eleventh annual meeting in Trenton on Thursday and Friday of last week.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 24, 1885:

DISEASES.	Week ending Nov. 17.		Week ending Nov. 24.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	0	2	2
Typhoid fever	25	8	33	9
Scarlet fever	21	0	39	9
Cerebro-spinal meningitis	4	4	3	3
Measles	13	4	17	5
Diphtheria	59	28	72	23
Small-pox	7	2	7	2

The Woman's Hospital.—The annual meeting of the managers was held on Thursday of last week. The receipts were reported as less by $1,514.33 than those for the year before.

The Regulation of Medical Charity.—The conference held last week between members of the Charity Organization Society and representatives of several of the public medical institutions was well attended, and resolutions favoring the extension of the society's system to the various institutions were passed. A committee of conference was appointed, consisting of Mr. Hewlett Scudder, Mr. A. B. Ausbacher, Dr. S. O. Van der Poel, Dr. J. W. Roosevelt, and Dr. J. H. Emerson.

A Death from Yellow Fever is reported to have taken place at the Chambers Street Hospital last Sunday, the patient having been a fireman on a steamship which is said to have passed Quarantine the Thursday before and been reported as free from sickness. The vessel had touched at several ports in the West Indies.

The Edinburgh Infirmary.—The "British Medical Journal" learns that Mr. Skene Keith has been appointed a special assistant in his father's (Dr. Thomas Keith's) ward.

The Academy of Medicine in Ireland.—The "Medical Times and Gazette" states that Dr. Thomas Addis Emmet, of New York, has been elected an honorary fellow of the Academy.

The Death of M. Bailliere, the founder of the well-known Paris medical publishing house, is announced as having taken place last Saturday. He had reached the age of eighty-eight years.

The Death of Dr. William Frothingham.—On Thursday of last week Dr. Frothingham, a well-known physician of Washington Heights, was killed by the discharge of a pistol which he had undertaken to put in order for the purpose of killing a sick dog. The deceased was fifty-five years old, and had practiced at Washington Heights for twenty years. He was a member of several of the larger medical societies of New York, and was much esteemed in the profession.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 15 to November 21, 1885:*

Heger, Anthony, Major and Surgeon, member of the Army Medical Examining Board now in session in New York city, is relieved from the additional duty of attending surgeon in that city, to take effect when Joseph R. Smith, Lieutenant-Colonel and Surgeon, shall have arrived in New York and entered upon that duty. S. O. 267, A. G. O., November 19, 1885.

Elbrey, F. W., Captain and Assistant Surgeon. Sick leave of absence further extended six months on surgeon's certificate of disability. S. O. 263, A. G. O., November 14, 1885.

Strong, Norton, Captain and Assistant Surgeon. Relieved from duty at Fort Union, New Mexico, and ordered for duty as attending surgeon, Headquarters, District of New Mexico, and post surgeon, Fort Marcy, New Mexico. S. O. 171, Department of the Missouri, November 16, 1885.

Ewing, C. B., First Lieutenant and Assistant Surgeon, now at Fort Leavenworth, Kansas, ordered to proceed to Fort Reno, Indian Territory, and report to commanding officer for temporary duty in the field. S. O. 170, Department of the Missouri, November 13, 1885.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the week ended November 21, 1885.*

Yemans, H. W., Passed Assistant Surgeon. Promoted to be Passed Assistant Surgeon from November 1, 1885. November 14, 1885. Reassigned to duty at San Francisco, Cal. November 16, 1885.

McIntosh, W. P., Assistant Surgeon. Appointed an Assistant Surgeon. November 14, 1885. Assigned to duty at New Orleans, La. November 16, 1885.

Society Meetings for the Coming Week:

Tuesday, *December 1st:* New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Herkimer (semi-annual—Herkimer), and Saratoga (Ballston Spa.), N. Y.; Hudson County, N. J., Medical Society (Jersey City); Androscoggin County, Me., Medical Association (Lewiston).

Wednesday, *December 2d:* Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot County, Me., Medical Society (Bangor).

Thursday, *December 3d:* New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-Psychological Association; Obstetrical Society of Philadelphia.

Friday, *December 4th:* Practitioners' Society of New York (private).

Saturday, *December 5th:* Clinical Society of the New York Post-Graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Letters to the Editor.

THE GRENET CELL *VS.* THE CHLORIDE-OF-SILVER CELL FOR A PORTABLE GALVANIC APPARATUS.

156 Madison Avenue, *October 24, 1885.*

To the Editor of the New York Medical Journal:

Sir: While perusing a file of Journals which had accumulated during the summer months, my attention was caught by an article in your Journal of July 18, 1885, from the pen of Professor L. C. Gray, entitled "Two Valuable Aids in Electro-Therapeutics." As the subject was one which bore upon a field in which for some years I have been extremely interested and quite actively employed, I feel it my duty to correct some statements made in that article apparently on insufficient information. The article in question is written (evidently with great enthusiasm) in support of a portable galvanic battery made of chloride-of-silver and zinc elements, which (according to the author) so far surpasses all previous efforts of electricians that he says: "I am prepared to say that its general employment will mark a new era in galvano-therapy."

Now, let us see upon what facts the champion of such a remarkable invention (as this would seem to be) rests his claim for its universal recognition. If I should state in the commencement that I have intentionally omitted this form of cell from the list of those which I have depicted and recommended in my forthcoming work upon "Electricity in Medicine," and that I have done so for good and sufficient reason, I must either admit myself to be unacquainted with the progress lately made in electrical devices, or I must prove the soundness of my convictions. I prefer to attempt the latter.

The chloride-of-silver and zinc element as the basis of a battery is not new. Dr. Gray need not have written to foreign countries (as he states in his article that he has done) to obtain much valuable information respecting its rise and fall. The "chloride-of-silver battery" presented to the profession some years since by the Western Electric Company is practically the same as the one Dr. Gray now extols. True, it had glass cups in place of rubber ones (which cost more), and it lacked some other of the mechanical features described by Dr. Gray, although the latter are but copies or slight modifications of identical devices employed by other manufacturers of this city and of Europe. Its excitant was the same, the elements were the same, the cell was practically the same, and the battery was light and easy to handle (the only claim, in my opinion, which it ever had to "universal recognition").

This battery was sold extensively at first by a reputable firm in this city, and probably equally so elsewhere. This firm finally declined to continue selling it, and I am informed that the Western Electric Company has since discontinued its manufacture. So much for the history of the "chloride-of-silver battery" in this country from a practical standpoint. Dr. Gray admits that a Mr. Schoth, of Europe, has thus far failed to make a satisfactory battery with this form of cell—although he has been "experimenting with them at Dr. De Watteville's instance." Dr. Gray has tried his own battery but a few months; yet, because it works and is light, he gives it his unqualified indorsement. Is not the conclusion on its face rather a hasty one?

In the second place, this type of cell has a low electro-motive force, and generates but a *small quantity* in the battery Dr. Gray describes. The elements are costly, and are not regarded by well-posted electricians as possessing the durability Dr. Gray claims for them. It is true that the silver can be reclaimed (when the fluid is saved after the elements are consumed and subjected to certain chemical processes), but few physicians would go to that trouble for the purpose of saving a few dollars. Dr. Gray estimates that it will cost "about $8 per year" for repairs. Even at this very low estimate, the battery becomes decidedly expensive. He fails, moreover, to state the first cost of the instrument—so that comparison on that score with the cost of other batteries made by reputable manufacturers is impossible.

In the third place, great stress is laid by Dr. Gray upon the light weight of the battery (9 to 12 pounds). Personally, I fail to see why a physician who owns a buggy and horse need to care much if a few pounds of weight are or are not dispensed with, provided that he can carry the machine easily from the carriage to the house of each patient without assistance. With a portable battery composed of the Grenet cells he gains (1) cheapness of construction; (2) a fluid which can be renewed when required at a cost of a few cents; (3) a cell whose elements last a long time and cost about ten cents each to replace when they at last are consumed by the fluid; (4) a high electro-motive force; (5) a considerable quantity of electricity—if the elements are of the usual size; (6) an easy way of overcoming

polarization when the battery is in use; (7) a clean instrument which, when properly made, will not spill the fluid; (8) the ability to select the cells employed from any part of the battery; and (9) a simplicity of construction which admits of repair by the physician himself if he possesses a screw-driver and a pair of pinchers.

Some months ago Dr. Brown, of this city, exhibited, at a meeting of the Clinical Society of the New York Post-Graduate Medical School, the very battery which Dr. Gray now presents as novel. The remarks of Dr. Brown were published, without the cut, in the "New York Medical Journal" in February, 1885. If I am not mistaken, Dr. Brown had been instrumental in calling the attention of the manufacturer to several of its best features.

In closing, I would say that the sentence in Dr. Gray's article which impugns the many advantages claimed for the Grenet cell, both by myself and others, for a portable galvanic apparatus, is not in accord (as far as I can learn) with the experience of thousands who are to-day using this form of cell in Europe and this country. It seems to give universal satisfaction when properly managed and cared for.

Respectfully yours,

A. L. Ranney, M. D.

A NEW ANTISEPTIC LIGATURE.

Jersey City, *October 19, 1885.*

To the Editor of the New York Medical Journal:

Sir: Ligatures have been used for many years for bringing together and retaining solutions of continuity, also for the ligation of blood-vessels. They have been made from a number of materials, such as silk, linen, catgut, silver and iron wire. Physicians prefer one or the other, as their experience or judgment may dictate. Claims have been made for this or that particular ligature, in some cases, as being superior to the others.

In solutions of continuity the principal points of a good ligature are ease of application, a ligature that will hold when properly applied, and of a non-irritant character, so that it can be left in the wound as long as necessary—*i. e.*, until the edges adhere, without exciting undue inflammation. Silk for ligatures has been used more than any other material, and, as a rule, has answered the purpose; but, after a few days in the tissues, it absorbs moisture, causing pus to form, which provokes a discharge from the wound, and thereby tends to prevent, in some cases, union by first intention. Before the silk is used it is coated with bees-wax, to keep it firm and prevent the thread from slipping in the surgeon's hand. I have for some years used shoemaker's wax for coating silk ligatures, which is *highly* antiseptic, and can be left in the wound a *much longer time* than by using bees-wax. To show the antiseptic nature of shoemaker's wax, I will give you the composition as obtained from an intelligent shoemaker, who has made it for himself and others: Rosin 1½ lb., pitch 1 lb., melted together in a vessel over the fire; remove and then add half a pound of Archangel tar (common); the whole to be mixed to a proper consistence. As I consider this an improvement on the usual method of coating ligatures with bees-wax, and am not aware of its having been used for this purpose, I wish to make it known through your journal.

James Craig, M. D.

THE NAMES OF THE ENCEPHALIC ARTERIES.

Ithaca, N. Y., *October 24, 1885.*

To the Editor of the New York Medical Journal:

Sir: The report of my paper On a Seldom-described Artery (*A. termatica*), with Suggestions as to the Names of the Principal Encephalic Arteries, in the "Transactions of the American Neurological Association," pp. 33, 34 ("Journal of Nervous and Mental Disease," vol. xii, No. 3, pp. 348, 349, July, 1885), contains an error, due to my own inadvertence, which can be most effectually corrected if you can spare the space for the following table, as amended. Instead of two cerebellar arteries, there are three, *superior*, *anterior*, and *inferior*, the mononymic new names for which are *præcerebellaris*, *medicerebellaris*, and *postcerebellaris*, and the English paronyms of these, *precerebellar*, *medicerebellar*, and *postcerebellar*.

Common Latin names.	Proposed names.	English paronyms.	Abbreviations.
Vertebralis.	Vertebralis.	Vertebral.	*vrtb.*
Basilaris. (*az.*)	Basilaris.	Basilar.	*bslr.*
Cerebellaris superior.	Præcerebellaris.	Precerebellar.	*prcbl.*
Cerebellaris anterior.	Medicerebellaris.	Medicerebellar.	*mcbl.*
Cerebellaris inferior.	Postcerebellaris.	Postcerebellar.	*pcbl.*
Cerebralis anterior.	Præcerebralis.	Precerebral.	*prcb.*
Cerebralis media.	Medicerebralis.	Medicerebral.	*mcb.*
Cerebralis posterior.	Postcerebralis.	Postcerebral.	*pcb.*
Communicans anterior. (*az.*)	Præcommunicans.	Precommunicant.	*prcm.*
Communicans posterior.	Postcommunicans.	Postcommunicant.	*pcm.*
Choroidea anterior.	Præchoroidea.	Prechoroid.	*prchrd.*
Choroidea posterior.	Postchoroidea.	Postchoroid.	*pchrd.*

I have no mononym to propose for the very awkward dionymic eponym, *Circulus Willisii* (circle or pentagon or hexagon of Willis), but one is certainly desirable.

In this connection, permit me to add that in the paper On Two Little-known Cerebral Fissures, following the one just named, on pages 350 and 351, *neutromesal*, *callossal*, and *hypocampal*, should be *ventromesal*, *callosal*, and *hippocampal*, and on page 352 *hippocampal* should be included with the "fissures mainly or partly mesal."

B. G. Wilder.

North Brookfied, Mass., *November 18, 1885.*

To the Editor of the New York Medical Journal:

Sir: Are not the numerous remedies dispensed by druggists becoming a serious usurpation of physicians' practice? I requested a druggist to keep on hand a preparation of bromo-caffein, which I wished to prescribe for headaches, which, by the way, is an excellent remedy in the *beginning* of a sick headache. I now fear that my opportunities for prescribing the remedy are lessened, as I doubt not the druggist recommends it to others, who otherwise would apply to a physician. Ought not the druggists to be informed through their journals as to their duty in this matter, or shall physicians, as the evil increases, have to dispense their own medicine in self-defense?

Very respectfully,

J. Garst, M. D.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of November 19, 1885.

The President, Dr. A. Jacobi, in the Chair.

A Section in Laryngology.—A motion looking to the establishment of a Section in Laryngology was adopted.

The Health Department.—A letter from Mr. James Gallatin was read by the secretary, by which it appeared that the Board of Health of New York city had asked for a considerable increase in the annual appropriation over that for last year, whereas the amount allowed by the commissioners fell very considerably below that sum. In view of this fact, there was danger of the efficiency of the board being crippled by the reduction of the salaries of those who did the principal work. He hoped the Academy would exert its influence toward lopping off sinecures

and toward having nuisances corrected without the additional expense attending repeated inspections by the health authorities.

Dr. Gouverneur M. Smith had nothing to say with regard to the wisdom of reducing the appropriation called for, but with regard to other points brought out in the letter he thought we should speak, and therefore offered the following resolutions:

Whereas, It is a generally recognized fact that the value of the work of the Health Department of the City of New York depends largely upon the presence therein of competent medical men, and,

Whereas, It has been declared expedient that some reduction should be made in the expenditures of the department during the coming year;

Resolved, That it is the sense of the New York Academy of Medicine that said reduction should be effected in such a way as not to impair the usefulness of the department either by the dismissal of any of the competent and experienced physicians now in its service, or by lowering their salaries below a fair and equitable rate.

Dr. Fordyce Barker thought there was nothing in the spirit of the letter, nor in the spirit of the resolutions, which would not be for the best interests of the medical profession. As to how far the expenditures might have been injudicious, and how far the appropriations might be diminished, he was not able to speak, but there was no doubt that for the interests of all concerned the board should secure the services of physicians of integrity and ability, and then see that they were amply paid. He seconded the resolutions, and they were adopted without a dissentient voice.

The Annual Address: Pathfinding in Medicine.—Dr. Henry D. Noyes then read the anniversary address. He had been impressed with the thought that further advancement in medicine must depend upon acute, exact, and deep research. Clinical observation had done much toward advancing medical knowledge, and it promised still to do good work in the form of collective investigation, but it must be supplemented by work in the laboratory. Indeed, he laid greatest stress upon the importance of laboratory research, and instanced the discoveries made by Virchow, Helmholtz, Pasteur, and others. The value of exact and deep research made by some persons of restricted opportunities had been well illustrated in the case of that brilliant scholar, Dr. Thomas Young, to whom the author paid a warm tribute of respect. He also paid a tribute of honor to Mr. Palmer, who overcame all obstacles and finally succeeded in becoming master of Oriental and other languages, which was turned to practical use in winning the friendship of desert tribes which had harassed the workers on the Suez Canal. But to build and equip a laboratory for scientific investigation involved a large outlay of money. It was for this reason that in Europe, where governments built and sustained laboratories, and paid professors who had risen to eminence in special departments of their profession for taking charge of them, more numerous discoveries had been made, especially in bacteriology. If the people of this country, and especially the wealthy people of New York, were made to see the need of opportunities for exact research in order to advance the health interests of the human race, many would be found who would contribute of their wealth toward the building and equipment of laboratories. Proof of this view already existed in the munificent gift of Mr. Vanderbilt to the College of Physicians and Surgeons, and in the building of the Carnegie Laboratory.

Dr. Fordyce Barker spoke of the pleasure with which he had listened to anniversary addresses before the Academy of Medicine many years ago, but more recently, on account of the inefficiency, he said, of Dr. Jacobi's predecessor, the custom had been dropped and had not been revived until the present year. He was glad that the president had renewed it, and moved that a vote of thanks be extended to the orator of the evening. The motion was unanimously carried. Dr. Barker expressed great hope that ere long the Academy would be able to supply a laboratory for use by those engaged in special investigation. Surely a city having so many wealthy people as New York would not allow this need to be long felt.

NEW YORK SURGICAL SOCIETY.

Meeting of November 10, 1885.

The President, Dr. Robert F. Weir, in the Chair.

Neuralgia of the Superior Maxillary and Inferior Dental Nerves; Resection; Cure.—Dr. William T. Bull presented a man showing the results of two operations — one performed upon the superior maxillary, and the other upon the inferior dental nerve—for obstinate neuralgia. These operations had been performed fifteen months before, and, as there had been no return of the trouble whatever, he thought the case might be regarded as one of cure.

A night watchman, sixty-two years of age, was admitted to the New York Hospital July 29, 1882. For several years he had had at intervals some pain in the right side of the face, which within a year had become more severe and almost continuous. He was rheumatic, had not had syphilis, and the history of malarial disease was doubtful. All sorts of medical treatment had been resorted to, and many teeth in both the upper and the lower jaw had been extracted. When admitted he was suffering from the same pain, which was partly controlled by hypodermic injections of morphine. There were tender points over the infra-orbital and mental foramina, and over the condyle of the jaw. He was slightly emaciated, and could not eat solid food, and also had pain in talking.

August 11, 1884.—The superior maxillary was exposed in the floor of the orbit and three fourths of an inch removed. The artery was divided and bled sharply. It was stopped by a plug of catgut which was continuous, with a few strands emerging from the center of the wound. Peat and bichloride dressing were applied. The wound healed primarily in four days.

18th.—The inferior dental nerve was exposed by a vertical incision over the ramus of the jaw and by chiseling through the outer wall of its canal (Warren's operation). The incision was placed low enough to avoid Stenson's duct; the fibers of the masseter, with the periosteum, were raised with the elevator, and the upper angle of the wound was strongly retracted. It was a narrow wound to work in, but there was little difficulty in removing a rectangular piece of bone, one fourth by three fourths of an inch in area. Three quarters of an inch of the nerve were removed. In separating it from the artery the latter was wounded and tied with catgut. A small bone-drain was left in the wound, which was treated like the other. At the end of a week, when the dressing was removed, the wound had healed except at the orifice of the tube, and this closed promptly under an iodoform scab.

From the time of the operation the man experienced no pain whatever in the face, and there was complete anæsthesia over the areas supplied by the nerves. There was no facial paralysis. Now, fifteen months after the operation, he continued perfectly well. There had been a dull aching in the lower jaw in damp weather, but it was trifling in degree, and did not increase in either frequency or severity.

Dr. R. W. Amidon had kindly examined the man lately, and stated: "I tested the sensibility with a faradaic current and a single-wire electrode, and found complete anæsthesia on the right side of the face over an area included between two lines running from the outer and inner angles of the orbit downward to the line of the chin. It does not reach far back on the cheek, or

much under the chin. It does not reach the lower palpebral margin, nor *quite* to the median line on the nose. In the lips and chin it extends *exactly* to the median line. It involves the gums and what teeth there are in the lower jaw on the right side up to the median line. At the outer, upper, and nasal borders of the area the anæsthesia shades off into normal perception. On the lips and chin the anæsthesia is complete up to the median line, and the transition to normal sensibility is sudden. There is no anæsthesia of the palpebral conjunctiva of the right lower lid or the right internal canthus, or the gums of the upper jaw, or the tongue. There is no paralysis of any facial muscle. He has complained of his sight being weak since the operation. I find the fundus normal and the vision good, but with the prism-test I find that he has an insufficiency of the interni (probably the right) of 5° for distant vision and 12° for near vision, and he reads much better with a prism to correct that.

"*Query:* Did you injure, during the operation, the branch of the inferior division of the *third* nerve which passes under the optic nerve to the right internal rectus?"

The PRESIDENT said there was one point worthy of special note in Dr. Bull's case, and that was the extremely satisfactory result from an operation performed externally instead of dividing the inferior dental and maxillary nerves within the mouth. He thought the internal section, made after Paradacini's method at the spine of Spix, was rather an unsatisfactory operation. It was somewhat difficult to perform, and the amount of nerve extracted was comparatively limited.

Dr. F. M. MARKOE said he had had a satisfactory result in a similar case, but the operations were not performed at the same time. Quite a number of years ago he operated upon a patient who had suffered for a long time and severely with neuralgia in the parts supplied by the inferior dental nerve. He trephined the canal and cut out about one inch of the nerve, and with perfect success. About three years afterward the patient came to him with neuralgia of the superior maxillary nerve, and he performed the same operation, cutting out about one inch of the nerve, going back to the point where it entered the antrum, and destroying the nerve as far back as was possible with the point of the scissors, and again with success which lasted a little more than two years, when the patient returned with some slight neuralgia affecting the region supplied by the supra-orbital nerve. The man was unwilling to undergo further operation, and disappeared from observation. Up to that time, however, covering a period of five or six years, he had experienced perfect relief.

Remarks on Excision of the Hip.—Dr. L. M. YALE then read a paper with this title. [See page 593.]

Dr. MARKOE said the paper was so statistical in character that there was hardly room for discussion, and that it contained an extremely interesting and very valuable accumulation of results obtained by different operators. So far as he had been able to discover, nothing appeared in the paper which indicated that the danger of tubercular infection was either greater or less in those operated upon than in those not operated upon.

Dr. YALE said that was the conclusion, except in this one instance. Caumont had analyzed all the cases treated in every way, between one and two hundred in all, and drawn the conclusion that tuberculosis was in no way relieved by exsection; indeed, one third of the patients died after excision, and one fifth in suppurative cases without exsection. Of course that was not a sufficiently large number of cases to settle the question.

The PRESIDENT asked if we were not premature in laying much stress on general infection after an operation upon a tuberculous bone or joint, as it was a matter which had not been brought to our notice, especially with reference to later pathological developments, until within the last two or three years. He would feel unwilling to accept such statements as conclusive until a larger experience had been obtained. This inference, if received as final, would cut off all attempts at operative interference for the purpose of getting ahead of tuberculous disease in bones and joints, and would render such operations unjustifiable.

Dr. C. T. POORE thought that private statistics should not be put in comparison with hospital statistics, because statistics derived from patients among the better classes were more favorable to the expectant plan of treatment. He did not believe that statistics of excision of the hip joint in hospital cases in general would show more than 33 per cent. of mortality, and in the same class of children treated expectantly without operation, his impression was, the mortality was greater than after excision. He was unable to see how one could determine, while persistent suppuration existed, whether or not he had to deal with simple caries of the joint or with a sequestrum which could not be removed without an operation. Besides, it was a serious question whether many patients with extensive disease of the acetabulum would ever get well without an operation, and whether an operation in those cases would remove that source of danger.

Dr. F. LANGE thought it generally conceded that a comparatively large percentage of patients with hip-joint disease would entirely recover under proper conservative treatment without excision of the joint. Even extensive destruction of bone did not preclude spontaneous recovery and a comparatively good functional result. He had observed so much destruction of bone that at last the trochanter was considerably above Nélaton's line, still without noticeable suppuration, and at the end with some mobility and a very useful limb. He thought it so much a point of experience as to whether in a given case one should follow out conservative treatment, or resort to more radical interference, that only the long-continued observation of a large material might entitle us to draw general conclusions. He must say that, as a principle, he was rather inclined to push the conservative treatment as far as possible, and his impression was that, even in cases presenting a more serious aspect, if only all the indications of hygiene and orthopædy were fulfilled, and retention of pus prevented as much as possible, good results could be obtained. Further, he thought that, if by consequent general treatment one succeeded in altering in a favorable way the constitution of the patient and in checking the progress of the local tuberculous process, any kind of surgical interference would be followed by more satisfactory results so far as complete recovery was concerned. Though feeling convinced that small particles of necrosed bone might be absorbed by the action of vigorous granulations, it was beyond doubt that a large percentage of patients would not recover entirely unless tuberculous sequestra were removed. Hence eventually in these cases excision had to be considered. He had repeatedly tried to avoid total excision, and to perform more of a sequestrotomy, but he must say that in all the cases but one he had been obliged to add excision of the upper end of the femur in order to get sufficient access to the diseased parts to enable him to remove with some degree of certainty the structures involved. In the one case above mentioned, in which several tubercular sequestra were removed from the anterior aspect of the acetabulum without touching the head of the femur, except to scrape away quite an amount of granulations, healing apparently took place, but it had not been under observation a sufficient length of time to enable him to determine whether recovery was permanent. He regarded the necessity of removing so much bone in excision of the hip joint as a great drawback to the operation, and did not think that the amount of shortening was so little as was

generally assumed. The question, what was the amount of shortening in adults who at an early age had been subject to excision of the hip joint, was not settled yet, and was worthy of careful investigation. Suppose we had a young patient with tuberculous osteitis of the acetabulum, and we removed, as might become necessary, a large portion of that bone, besides the separation of the shaft of the femur above the trochanter minor. In such a case we might have three or more inches of bone in its length lost, and, in addition to that, have abolished what additional growth might have come from the preservation of the upper epiphyseal cartilage. One ought to state how much that represented in the adult, in order to fix more accurately the question of indication for total exsection. The latter would of course always exist where the operation had to be done as a means of preserving life, and he thought that the standpoint of a good many surgeons and orthopædists, as a matter of principle, not to do any exsection at all, was identical with sacrificing a certain number of lives which otherwise might be saved. Especially the results of orthopædists were not absolutely conclusive, because in the majority of the worst progressive cases the patients did not apply to them, or eventually gave up their treatment in order to search for some more speedy relief. Regarding the very important question of functional result, he was not able to give a decisive answer. He had had some very good results after excision, and other cases in which after excision recovery was incomplete, or the functional result deficient. He had observed in several cases where a great portion of the acetabulum had had to be removed, in spite of consequent abduction during the after-treatment, that the shaft did not find a favorable point of support. One was able to make out in such cases a certain amount of slipping of the bones against each other, according to the more or less strong and tense fibrous connection; and he must further say that he was not convinced yet that, under all circumstances, a patient with a movable joint after excision was better off than one with ankylosis in good position. The latter, with a slight amount of flexion, would always have a safe gait, and was not deprived of the advantage of being able to sit. Besides, his limb would probably not be so short as that of the former, who, to be sure, might occasionally offer an excellent result, at other times an incomplete one. He also thought one point worthy of attention, namely, whether the position of the limb after excision, as well as after conservative treatment, was a lasting one. Eventually, after a year, perhaps after a good many years, an unfavorable position might take place. He had once within the last seven years seen general tuberculosis follow excision of the hip, apparently caused by the operation. The latter was done at an early stage of the disease. There were several sequestra belonging to the head of the femur, and the patient died, in the third month after the operation, of tubercular meningitis.

Dr. Yale said, with regard to the amount of shortening which might occur, that, according to Ollier's experiments, if it was assumed that the growth from the upper epiphysis was absolutely abolished, it was possible that, with the ordinary growth from that extremity of the femur, about nine centimetres might be lost. To that there might be added the atrophy from inactivity. He had measured many cured patients, some of whom had had abscesses, and others none, with regard to the different sources and amount of shortening. He had seen a tibia in a coxalgic person fall behind one inch or more, and it was fair to presume that the diminution in the growth of the femur was quite as much. If that was added to the other, it was possible that several inches might have been lost from simple inactivity. The amount of functional use which a limb might have with ankylosis after an extensive disease of bone had recently been brought to his mind by the case of a patient who, fifteen years before, had come under his care with an abscess which had been totally neglected. There were many fistulæ, and in the spring of 1871 he contemplated excising the joint, and asked the opinion of Dr. Sayre, who said that excision would do but little good on account of the great amount of disease of the pelvic bones. He therefore treated the case as best he could without resorting to operative interference, and the patient recovered with ankylosis, and was now a teacher in one of the public schools, although she still had six sinuses about the hip, which discharged more or less. The limb was in very good position; the actual shortening in the femur was an inch and a quarter, in the tibia about one inch, which is partially compensated for by tilting of the pelvis, and the remainder is nearly made up by super-extension of the sound limb; and practically, therefore, she walks with a shortening of only about half an inch, and locomotion is with only a very slight limp. He also recalled the case of a young man who, after he was cured, had thirteen cicatrices about the hip, and he was, when last seen, able to take an active part as a member of a baseball club.

A Urinary Calculus spontaneously fractured in the Bladder.—Dr. J. C. Hutchison presented a specimen which had been removed by bilateral lithotomy from a man twenty-three years old, who gave the history of stone in the bladder beginning when he was five years old. His general health was excellent, and he had always been able to attend to his business without much suffering until he began to drive a cart in the city of New York, when he experienced considerable pain in the bladder after a long day's drive over rough stones. Three weeks before he applied for treatment his symptoms suddenly grew worse, and the pain was so great that he was compelled to give up work. On exploration of the bladder with a searcher, the speaker at once detected a calculus. An instrument had never before been introduced into the bladder. Bilateral lithotomy was performed, and the two fragments of stone shown were removed. The patient made a satisfactory recovery. The surface of the stone showed no marks of an instrument with which it might have been broken, and the fractured surfaces were not covered with urinary deposits or smoothed by attrition, showing that the fracture was quite recent. All the evidence went to prove that the fracture was spontaneous, that it was the result of forces acting from within, and that it occurred at the time there was a sudden increase of pain in the bladder—three weeks before the operation. The stone was composed of calcium oxalate, with a uric-acid nucleus. It weighed 859 grains, was disc-shaped, measured an inch and a half in its transverse and an inch in its vertical diameter, and its surface was smoothly mammillated.

Dr. Ord,* in a paper read before the London Pathological Society, had expressed the opinion that there were three methods by which a calculus might spontaneously fracture: 1. From forces arising within the calculus itself; "in an altered state of the urine the nucleus becomes swollen, and acts as a bursting charge in a shell." 2. From molecular disintegration. 3. From weakness of the layers within the crust, allowing its fracture. The speaker could not understand how either of these methods could have caused the fracture in this specimen, nor had he any satisfactory explanation to offer.

Dr. Hutchison also presented twenty-two calculi removed by median lithotomy from a gentleman sixty-six years old, on on whom he had performed litholapaxy two years before. They varied in size from that of a pea to that of a hazel-nut; the surfaces were fissured, but not rough, and of a light-red color. A section of one was made for examination. It was composed

* "British Med. Jour.," May 10, 1879, and September 7, 1878.

mainly of uric acid, with a small amount of calcium phosphate. The total weight when removed was 478 grains. The patient recovered, but died some time afterward from causes not connected with the bladder. The speaker also showed the fragments removed from this patient two years before by rapid lithotrity. They weighed 225 grains, and were composed of uric acid and calcium oxalate.

Dr. POORE presented two small calculi removed from a child who was operated upon in May last by median lithotomy. The child was three years and a half old, and the second operation had been performed in September last.

The PRESIDENT asked if the child had suffered very much after the first operation.

Dr. POORE replied that the father, although perhaps his statement could not be accepted without allowance, had said that the child suffered a great deal after it left the hospital where the first operation was performed. At the time of its discharge after the last operation the child had no bladder symptoms.

The PRESIDENT said he had asked the question because it was well known that in the old subject two stones not infrequently existed and escaped detection. One case he recalled particularly, in which the patient was operated upon by the late Dr. Van Buren, and got a great deal of relief; and then pain came on again, and lithotomy was performed one year afterward by the late Dr. Buck. At the second operation a stone as large as the original one removed by Dr. Van Buren, of about the size of a walnut, was removed, and there was no evidence of facets upon its surface nor in its internal structure, and the explanation of the presence of the second calculus was found in the fact that an unusually large bar between the mouths of the ureters divided the bladder into two parts. Dr. Buck had been much struck by this condition, found at the time when he operated, and, as the patient complained about two weeks afterward of some pain, he anæsthetized him again, made another search, and found a small fragment of a calculus which was lodged in one of the irregularities of the prostatic portion of the urethra.

Dr. A. C. POST had met with two cases in which there was contraction of the bladder between two calculi so that the stones could not come together. His cases occurred in young subjects. In each case one calculus was near the urethral orifice of the bladder and the other was far back in the cavity, and there existed a contraction of the bladder between the two which could be felt with the finger.

Fistula in Ano.—Dr. LANGE directed attention to one way of treating fistula in ano, namely, cutting the entire canal out and sewing up the wound. In most cases it was a simple procedure, and he would be much obliged if the members of the society would try it. He had adopted it for the first time about two years before in the case of a woman who had a deep-seated fistula. In that case he had a complete result, and the patient recovered in about fourteen days. He had tried it in a limited number of cases, but he had not succeeded in all; yet he thought that, with improved technique, the results would become better. So far, at least, the results were encouraging. Having a probe in the canal, he dissected all about the probe and cut the entire fistulous canal away, including some of the tissues surrounding it, and then, with a catgut étage suture, closed the entire wound, and besides inserted several silk sutures around the whole mass, as after other plastic operations, to relieve tension and to prevent eventual separation of the lips of the wound in consequence of too early absorption of the catgut.

The PRESIDENT said he had performed this operation four times with satisfactory results. In one instance the fistula ran from the labium to the rectum. His first knowledge of the operation was obtained from the "Transactions of the American Gynæcological Society," and from a Western surgeon who reported a number of cases.

Dr. MARKOE had performed the operation twice by scraping out the fistula, but he had not got good results.

Dr. A. G. GERSTER had employed this method in a limited number of cases, and, as Dr. Lange had stated, with some good results and with some failures. He thought the method applicable in cases where the fistula was simple. Where, however, there were several fistulæ crossing each other, as occasionally occurred, and running perhaps in a spiral line around a part of the circumference of the rectum, and where, after removal of all the lining of these different canals, a complicated wound remained, the results had not been very satisfactory, the relations of the wound being such that absolute contact of all the surfaces could not be brought about, and accumulations of secretions with retention in pockets frustrated primary union. But certainly in simple cases, however deep, up to a certain extent, the method was a rational one, and it shortened the time of cure very considerably.

NEW YORK STATE MEDICAL ASSOCIATION.

Second Annual Meeting, held in New York, Tuesday, Wednesday, Thursday, and Friday, November 17, 18, 19, and 20, 1885.

(*Concluded from page 584.*)

Wednesday's Proceedings.

A Communication from the American Medical Association, regarding certain proposed uniform State legislation, was referred to a committee of three, to report to-morrow.

The Discussion on Pneumonia was resumed after certain other business had been transacted. Dr. CHARLES G. STOCKTON discussed in a brief paper the seventh question propounded by Dr. Flint, and said he thought the special manner in which the temperature should be lowered would depend upon the individual case; a single antipyretic would not answer in all cases. He had sometimes used quinine and antipyrine successively in the same case. Regarding antipyrine, he recommended its use in from fifteen- to twenty-grain doses once in from eight to twelve hours. When so used it had never produced any toxic effects upon the heart, and it had had the desired effect upon the temperature.

Dr. E. D. FERGUSON's experience with antipyrine had been similar.

Dr. J. G. ORTON discussed the eighth question in a brief paper. He had never seen an unqualified case of relapse of acute lobar pneumonia during or shortly after the period of convalescence, but one attack seemed to predispose to subsequent ones in the same lobe. He thought pneumonia was a non-infectious essential fever. He also spoke of complications and diseases to which pneumonia predisposed.

Dr. F. E. HYDE had in several cases of acute lobar pneumonia found evidence at the autopsy that there had been early and persistent thrombosis as well as embolism of the veins, and in two cases there had been embolism in the arteries as well. This condition he thought occurred more frequently than was supposed, and we could see why remedial measures proved of no avail, and why death occurred so early in the course of the disease.

Dr. SHELDEN and Dr. ROSS also discussed the paper.

The Medico-Legal Bearing of Pelvic Injuries in Women.—Dr. ELY VAN DE WARKER, of Syracuse, read a paper with this title, in which he said that actions at law to recover damages for injuries sustained to the pelvic organs in women were becoming quite frequent and involved large sums of money; they were usually brought against corporations, particularly cities and villages, and railroad companies. He cited three

illustrative cases, by which it appeared that the facts of the case, could they be obtained by a thorough medical examination, were in favor of the defendant, but the verdict was likely to be in favor of the complainant. Some of the women conscientiously but erroneously attributed their symptoms to the injury sustained, but most of the cases were of a fraudulent nature. In all, perhaps, there would be found a history of previous pelvic inflammation, or affections which would fully account for the symptoms present. The impossibility of a fall of some nature, which was the usual accident in these cases, producing such concussion of the healthy uterus and pelvic organs as to cause permanent displacement of the womb, or swelling, pelvic inflammation, and abscess was evident to the physician but not to the simple juryman, whose sympathies were appealed to by a suffering woman, while the other party to the action was a heartless corporation with a supposed unlimited supply of money.

Dr. Williams, of Boston, and Dr. Alonzo Clark, of New York, were at this point introduced to the meeting.

An Address on Some of the Relations of Physiology to the Practice of Medicine was read by Dr. Austin Flint, Jr., who said that physiology was the only rational basis of scientific medicine; this was true even if we used the term medicine in its widest signification, including in it the practice of surgery, gynæcology, and pathology. A knowledge of anatomy and physiology was a most important requisite in making a correct diagnosis. The necessity of a knowledge of physiology was evident in the study of valvular lesions of the heart, for our ability to diagnosticate heart lesions depended upon our familiarity with the functions of the heart and the sounds produced by the blood current in health. Dr. Flint analyzed the heart-sounds in different diseased conditions of the heart, in proof of his assertion that a knowledge of physiology was an important element in scientific medicine. In the same line he cited certain affections of the digestive tract, Beaumont's observations upon digestion within the stomach through a gastric fistula, the discovery of vaccination by Jenner, of the circulation of the blood by Harvey, of the manner of bacteria cultivation by Koch, etc. Regarding bacteria as causes of disease, the theory offered wide possibilities, and it was not improbable that methods of prevention and treatment of disease would now be discovered which would be of the greatest benefit to the human race. Methods of bacteria cultivation might also prove of value in the study of the physiology of the fluids and functions of the body. Dr. Flint referred to an article on the subject of how to treat a fever as based on physiology, which he published in the "American Journal of the Medical Sciences" in 1879, and said that fever meant the rapid use of the heat-producing elements in the economy, and hence the importance of digestion of heat-producing foods during a fever to prevent the burning up of the system. Alcohol in fever was well borne, and temporarily was capable of taking the place of the elements consumed by hyperpyrexia. In phthisis with fever hydrocarbons should be given, such as starch, sugar, and cod-liver oil; alcohol was well borne by such patients.

Recto-Labial or Vulvar Fistulæ; their Causes and Treatment.—Dr. Isaac E. Taylor read a paper in which he spoke of the comparative rarity of the condition. It was very liable to begin with a vulvar abscess, depending upon an inflammation of the vulvar glands, perhaps excited by injury during coition, masturbation, labor, direct injury, or cold. A small tumor might exist in the labium prior to breaking down into an abscess, perhaps quite movable, and leading to the suspicion of a displaced ovary. The history of such a case, seen by the author, was given. The tumor constituting the suspected ovary broke, and gases and fæces escaped by the small opening. Huguier's plates were shown in illustration of the subject-matter of the paper. The pathognomonic symptom of vulvar fistulæ was the escape of air and thin fæces. The vulvar opening was usually small—perhaps so small that it could be found with great difficulty. As to the treatment, he adopted the ligature. The method was simple and efficient, and, in view of the great and serious difficulties likely to attend the use of the knife, he thought it deserved much more general employment. The elastic ligature was to be preferred.

After reading the paper, Dr. Taylor presented to the society a form of obstetric extractor given to the association's museum by Dr. Samuel W. Francis, of Newport. Dr. Taylor also presented a fœtal skull which showed the effects of molding during extraction from an equally contracted pelvis. The gifts were accepted with thanks.

Recurring Luxations.—Dr. Edward M. Moore then read a paper on this subject. That luxations were likely to recur he would not attempt to prove, for it was a well-known fact. Recurrence of the luxation took place often not as a result of violence, but of the action of different forces not connected with violence. Some replacements were maintained with great difficulty. Attention was then called to the tendency of recurrence of luxations in different joints, and to the manner of preventing this accident. To prevent it in the case of the clavicle, the elbow was to be thrown backward and retained in that position by binding the hand to the side by means of adhesive plaster, or, what was better, by means of a figure-of-eight bandage; thus the scapula would be carried nearer the vertebral column. Several interesting cases were related in which recurrence of luxation had taken place in the shoulder joint, and the manner in which the accident was apt to occur was pointed out. The reader's views with regard to luxations occurring in this joint had been made clear by certain experiments which he had performed after removal of the flesh about the shoulder, and bringing forces applied upon the arm and forearm to bear upon the ligamentous structures. His experiments illustrated incidentally how it was that, in many cases of sprains, or supposed injury to ligamentous filaments, the symptoms were as serious as and more prolonged than in fractures of bone; for, as had been shown in these instances, the ligament gave way only by taking with it a portion of the bone to which it was attached. In luxations at the shoulder, either upon the dorsum of the scapula or into the axilla, examples would be met with in which maintenance of reduction would be found difficult. The manner in which the luxation took place was by gravity allowing the arm to fall, especially if at the same time the arm was turned more or less forcibly outward. Touching upon recurrence of luxation at the hip joint, the author cited an interesting case which had come under his observation, and had been reported, with two others, by Bigelow, in which a soldier acquired the art of dislocating and replacing the head of the femur by a certain twisting motion of the body.

The Difference in the Symptoms of Strangulated Oblique Inguinal Hernia.—Dr. Hyde read a paper with this title, in which the following were some of the principal points brought out: 1. In proportion to the length of time an inguinal hernia had existed would the symptoms and signs of strangulation be mild and chronic. 2. In a case of long-standing inguinal hernia in which signs of stricture of the bowel were obscure, with no evidence of total destruction of the canal, it was often not safe to wait for fæcal regurgitation before deciding that strangulation existed. 3. When strangulation occurred at the first protrusion, the symptoms would be found to be more marked. 4. If hiccough and fæcal vomiting had existed from nearly the beginning of the symptoms, no time was to be lost; kelotomy should be performed at once. 5. If a swelling existed, with

symptoms of obstruction of the bowel, the patient complaining of severe pain in the abdomen, although of none in the tumor, but having hiccough, even if there was no marked general disturbance, a fair trial of taxis should be made, and, that failing to reduce the tumor, kelotomy should not be delayed. This remark was based on an interesting case, the history of which Dr. Hyde gave in detail. No fæcal vomiting occurred, nor any pain in the tumor even after taxis, but there was some pain in the abdomen, with hiccough. Because of the mildness of the symptoms the consulting physicians delayed the operation more than twelve days, and, when it was finally performed, the strangulation was found to have existed within the abdomen. The patient died. 6. If no strangulated portion was found within the external sac, the finger should be passed internally and adhesions sought for in the neighborhood of the opening. 7. Too long a trial of taxis before dividing a stricture should be guarded against, as it increased the liability to death. 8. After stercoraceous vomiting had set in, taxis should not be applied, but kelotomy should be performed at once, although the prognosis was unfavorable. 9. If, after the sac was opened, the omentum was found smooth, and no intestine could be detected, the omentum should be unfolded to learn whether it did not contain a strangulated portion of intestine. It was unfair to speak of kelotomy as a dangerous operation *per se*. The danger attending it was due to the condition of the sac and its contents, and to taxis and delay in operating.

Dr. J. W. S. Gouley read some notes on the subject of Dr. Hyde's paper, in which he stated the following conclusions: 1. When doubt arises respecting the existence of strangulation of the intestine or omentum in a case of incarcerated hernia, it is the surgeon's duty to give the patient the benefit of the doubt by at once resorting to the operation of kelotomy. 2. Delay in relieving the strangulation was often fatal, while kelotomy in a case in which no strangulation existed was not usually harmful. 3. Medicinal treatment was often delusive, and local applications, such as opium, tobacco poultices, ice, etc., were in most cases worse than useless. 4. Persistent taxis was infinitely more dangerous than kelotomy, and such taxis, even when it was followed by reduction, was often the cause of fatal peritonitis. 5. Another, though rare, effect of violent taxis was the reduction of the hernia *en masse* in its state of strangulation, and it was well known what the result was. 6. As a general rule, two minutes of gentle taxis, the patient being in a hot bath, would settle the question as to the possibility of safely reducing the hernia. 7. Therefore, it might be said with propriety that the less taxis, the less ice, the less other topical applications, the less opium, the less general or special meddlesome interference, which often did serious injury to the intestine, the better the chances of recovery in the event of kelotomy. This was particularly the case in femoral hernia. The speaker had abstained from incising the neck of the sac in femoral hernia, but had made divulsion by simply insinuating the index-finger through the free opening made in the sac until it entered the abdominal cavity, and had had no trouble in effecting reduction of the intestine, the object of the procedure being to avoid division of the obturator artery should it be abnormally situated. He agreed with Dr. Hyde that kelotomy was not *per se* a dangerous operation. Further, if it seemed necessary in a case of inguinal hernia, after kelotomy he would open the abdominal cavity in order to relieve the strangulated intestine.

Dr. Varick, of New Jersey, indorsed what the other speakers had said, especially as to the advisability of an early operation, and the importance of guarding against undue taxis. In his hospital he always proceeded at once to kelotomy, knowing that before the patient had reached the hospital taxis had been carried to a sufficient degree.

The Medicinal and Dietetic Therapeutics of the Common Forms of Chronic Intestinal Catarrh.—Dr. John S. Jamison read a paper supplementary to one read last year. It called out considerable discussion.

A Cursory Review of the Epidemic and Endemic Diseases of Sullivan County during the last Thirty-four Years was the title of a paper read by Dr. Isaac Purdy. During the first years of the period, commencing in 1850, pneumonia and fevers of asthenic type prevailed, in which it was common to bleed, and to employ cathartics, diuretics, and a depleting system of treatment, and this course seemed to be indicated as being followed by the best results. About the beginning of 1854 typhoid fever was heard from in the distance, and soon reached Sullivan County, and for several years pneumonia and other forms of disease took on a typhoid character, and this period was marked by the fact that in nearly all cases the asthenic form of disease showed itself; a depletory course of treatment was followed by the worst results. Close attention had to be given to the diet, to encouraging nutrition, and to checking excessive discharges. About 1860 diphtheria began to prevail in Delaware County, marched up the Delaware River, and existed in Sullivan County in the epidemic form for about five years, being very violent and carrying away many patients. The odor of persons suffering from the disease was peculiar, and could be recognized at a great distance from the sick-bed. In the author's opinion it was a constitutional, not a local affection, although the local deposit constituting diphtheritic croup was present. About 1862–'63 it was present in the form of black fever, petechial fever, etc., being in places very malignant. Afterward it again appeared as genuine diphtheria of the throat. In these cases they applied turpentine and sweet-oil to the throat at night with benefit. During a part of this period dysentery prevailed; first severe, then of mild type. Scarlet fever was present at intervals of about five years, sometimes of severe, sometimes of mild character. Measles had occurred at different periods, but in general required little treatment. Occasionally diphtheritic cases occurred up to the present time, but the contagion was generally brought from afar. Typhoid fever had continued to prevail more or less, especially in the autumn, and typhoid pneumonia during the winter, up to 1881. The spread of typhoid fever up the Hudson and its tributaries occurred at one period. The highest point was situated 1,200 feet above the level of the sea. The treatment consisted chiefly in moving the bowels, particularly with calomel, and then giving quinine.

The discussion which followed was lengthy and of a general nature, particularly with regard to the treatment of diphtheria.

Commercial Prescriptions.—Dr. Henry Van Zandt, the author of this paper, was of opinion that physicians should write their own prescriptions and have their medicines compounded by the apothecary or do the compounding themselves, and not depend upon the preparations coming from commercial houses, regarding the exact nature of which they must necessarily be more or less in doubt.

Prophylaxis.—Dr. Isaac de Zouche chose this subject for a paper, in which he pointed out the advantages of preventive over curative measures.

Thursday's Proceedings.

Officers for the Ensuing Year.—The nominating committee had named for president, Dr. E. M. Moore, of Rochester; for vice-presidents, according to districts, Dr. William Gillis of the first, Dr. H. Van Zandt of the second, Dr. Frederick E. Hyde of the third, Dr. Desault Guernsey of the fifth; for members of the council, from different districts, Dr. E. M. Lyon, Dr.

Ira H. Abell, Dr. Thomas Wilson, Dr. F. W. Ross, Dr. S. T. Clark, and Dr. E. S. F. Arnold. The secretary was instructed to cast the ballot, which he did in the affirmative, and the president declared the gentlemen named elected.

The Demodex Folliculorum as a Cause of Acne.—Dr. Fell, of Erie County, read a paper in which he described some rebellious cases of acne which had come under his observation and had finally yielded to treatment, the cure, he believed, bidding fair to be permanent. This opinion was founded on his views regarding the possible or probable ætiology of the disease. It was true his views were new, but, so far as his own observation had gone, they were substantiated by facts. In a large number of examinations of the contents of the acne tumors, he had always been enabled to find the *Demodex folliculorum*, usually from six to ten in number. While the presence of these mites in the skin was not of unusual occurrence, and had long been known, they had not been regarded as the cause of acne. He had found them in the pus or oil-globule, and not in the indurated matter. While their presence in small numbers might not give rise to apparent disease of the skin, he thought that when large numbers existed they might stand in the relation of ætiological factors of considerable importance.

The Communication from the American Medical Association.—The committee of three, appointed by the president to report on the communication, recommending that a uniform law be pressed for passage by the various State Legislatures, reported that it was inexpedient for the association to enter upon the discussion of the subject at the present time.

Oxygen in the Treatment of Pneumonia.—Dr. E. G. Janeway, by request, made some remarks on this subject before proceeding to read his address in pathology. According to his experience, oxygen inhalation in pneumonia was of marked benefit. It was especially serviceable in incipient cyanosis or just previous to this symptom; its use should not be delayed until cyanosis had become well marked. If employed at the proper time it would often be found to tide life over the critical point and lead the patient on to recovery. Dr. Janeway would also add to the discussion on pneumonia that he had seen one case in which the patient had a relapse at the end of a week, as much a relapse as the relapses of typhoid fever. He said, further, that he had seen a number of cases in which tuberculosis of the upper lobe of the lung had occurred in patients who had suffered from pneumonia, and he was of opinion that the attack of pneumonia had left the lung in a weakened state, fitting the soil for the development of tubercle bacilli.

The Address in Pathology.—Dr. Janeway then proceeded to read his address, which was devoted largely to the advances made in pathology, particularly during the past few years, and the relation of pathology to exact diagnosis and the ætiology of disease. The importance of the cultivation methods adopted by Koch, the value of Pasteur's discoveries regarding anthrax and hydrophobia, etc., received attention. The field for labor and new discoveries was still great, and offered excellent opportunities for able and progressive young men. The backwardness of this country in scientific discovery was attributed in large part to want of Government aid, such as was given in Germany and other countries of Europe. Special paths for investigation were offered in tetanus, anæmia, malignant tumors, lithæmia, etc. Dr. Janeway thought vaccination should be done, if possible, before the third day after exposure to small-pox if it was desired to abort the attack; otherwise it might be too late.

The Report of the Library Committee was read, by which it appeared that a room had been secured in the Carnegie Laboratory building. The entire number of volumes was about 3,450, and more than 4,000 pamphlets had been received. Some interesting specimens had been presented, which it was hoped would form the nucleus of a museum in connection with the library.

Exploratory Laparotomy for Gallstones.—Dr. W. W. Seymour gave the history of a case of gallstones in which the usual symptoms were present, but the gall-bladder could not be felt through the abdominal wall. Nevertheless, the patient's sufferings were such, and her health so reduced, that an incision was made for the purpose of removing the supposed stone or stones. The gall-bladder was found empty; there was a hard nodule involving the cystic and hepatic ducts, and, as it was thought that the symptoms were due to malignant disease, the abdominal wound was closed. Eight weeks later the patient died, decidedly emaciated and jaundiced. In the upper margin of the right lobe of the liver there was a cancerous patch; the gall-bladder was empty; the common duct was impervious; the junction of the cystic and hepatic ducts was involved in the hard mass, which was of the size of a hen's egg and continuous with the right lobe of the liver. The hepatic duct was enormously dilated, and filled with gallstones of the size of a peach-stone; an ulcerated opening led from the upper part of the hepatic duct into an abscess cavity, an inch and a half in diameter, in the right lobe of the liver, where a gallstone was found. The hard mass was cancer.

The Chlorides: Antisepsis a Prominent and Important Factor in their Medicinal Action, was the subject of a paper read by Dr. Nelson L. North.

The Causes of Failure in the Treatment of Urethral Stricture by Electrolysis.—Dr. Robert Newman then read a paper on this subject, in which he said that the method had been so successful in his own hands that he had not been aware of any failures until his attention had been drawn to a paper on the subject quite recently. He had then made some inquiries and found that failures did sometimes occur in the hands of those of little experience with the method. The cause of failures could be given in two words—bad management. This could be classed under three heads—incompetence on the part of the operator, errors in diagnosis, and faulty instruments. These headings were treated of at considerable length, the points being sustained by reference to letters, cases, and instruments.

Dr. G. C. H. Meier corroborated the author's statements from his own experience, and testified to the excellent results obtained by this method when properly carried out. It was true that it was not until he had assisted Dr. Newman in his public and private practice for some time that he had been enabled alone to give the patient the full benefit of the treatment of urethral stricture by electrolysis. The paper was also discussed by Dr. Manley.

Pelvic Hæmatocele; its Diagnosis and Treatment.—Dr. W. W. Seymour read a paper on this subject, which he had read at the branch meeting at Saratoga. A great many cases had occurred in his own and in his father's practice, going to show that pelvic hæmatocele was of much more frequent occurrence than was stated by most authors. Where there was a tendency to an increase in size, or to interference with the functions of neighboring organs, aspiration might give prompt relief. Aspiration failing, and suppuration taking place, he was disposed to make an incision *per vaginam* and irrigate.

The Action of Micro-Organisms upon Surgical Wounds.—Dr. Frederick S. Dennis read a paper on this subject. He drew a diagram, classifying bacteria, and pictured an operating-room to be disinfected before use by throwing hot steam into it.

Friday's Proceedings.

The History and Treatment of Thirty Cases of Diphtheria was the title of a paper read by Dr. Samuel W. Smith.

The great mortality from diphtheria was shown by figures obtained from the Board of Health of New York, by which it appeared that, out of an average of about 2,500 cases yearly for several years past, there had been a mortality of nearly fifty per cent., the rate of mortality varying slightly from year to year. In order to test the value of a given method of treatment, Dr. Smith had employed that adopted by Dr. Billington, described in a paper read before the New York Academy of Medicine. It consisted in syringing the nose and pharynx every two hours with a solution of chloride of sodium, a teaspoonful to a pint of warm water, to which Dr. Smith had added a teaspoonful of borax. The syringing should be done in a very thorough manner. In addition, the throat was sprayed with lime-water and a solution of carbolic acid, and tincture of chloride of iron and glycerin were administered, being alternated with chlorate of potassium. In the thirty cases there were five deaths.

Pelvic Hæmatoma.—Dr. GEORGE T. HARRISON read a paper in which he gave the history of a case, and treated of pelvic hæmatoma in a general way, taking up the questions of diagnosis, treatment, etc.

Cancer of the Kidney.—Dr. JOHN SHRADY read a paper in which he described a case of cancer of the kidney in a child, which had been reported in the proceedings of the New York Pathological Society. The differential diagnosis was considered. In a child the diagnosis was comparatively easy to make, but the rarity of the affection might cause the physician to overlook the true nature of the case.

On the Treatment of Spondylitis or Caries of the Spine by Partial Suspension and the Plaster-of-Paris Jacket, and the Treatment of Rotary Lateral Curvature by Gymnastics and Partial Suspension and the Plaster-of-Paris Corset.—Demonstrations by practical application in cases were made by Dr. LEWIS A. SAYRE.

The society then adjourned, to meet in New York on the third Tuesday in November, 1886.

During the session the following papers were read by title: "Antipyrine; its Power to diminish and occasionally entirely remove Fever," by Dr. W. S. Fuller; "The Significance of Non-traumatic Intra-ocular Hæmorrhage in Diseases of the Heart, Blood-Vessels, and Kidneys," by Dr. C. S. Bull; "The Relation of Drink to Insanity," by Dr. G. A. Blumer; "Tumors of the Jaw," by Dr. W. S. Tremaine; "The Treatment of Incontinence of Urine in Women resulting from Over-dilatation and Paralysis of the Urethra," by Dr. N. Bozeman; "Skin Flaps in Amputations," and "Umbilical Hæmorrhage in Infants," by Dr. U. C. Lynde; "A Case of Poisoning by Two Grains of Strychnine," etc., by Dr. W. Fitch; "The Treatment of Abscess," by Dr. J. D. Rushmore; "Chronic Catarrhal Gastritis," etc., by Dr. W. H. Thayer; "The Proper Disposal of Street Sweepings," etc., by Dr. A. H. Briggs; "Ergot, its Uses and Misuses," by Dr. J. K. Leaning; "Nutrition in Lithæmia," by Dr. C. G. Stockton; "The Modern Aspect of Therapeutics," by Dr. T. H. Manley; "The Vectis in Cross-Births," and "Pessaries and their Uses," by Dr. J. Hartmann; and "Notes on Contracture of the Bladder consequent upon Cystitis," by Dr. J. W. S. Gouley.

Miscellany.

The Case of the late Professor Panum.—Dr. D. Bryson Delavan writes to us as follows: The following history, communicated by Professor Frier to the Medical Society of Copenhagen, has been translated, prepared, and transmitted to me by my friend Dr. Holger Mygina, of Copenhagen. Besides the rare pathological importance of the case, its interest is still further enhanced by the fact that the patient was none other than Professor O. L. Panum, the distinguished and much-lamented President of the Eighth International Medical Congress.

Dr. Mygina's translation is as follows:

Professor Panum, who reached the age of sixty-four years and four months, had, on the whole, enjoyed good health. About ten years before his death a chronic bronchitis with frequent acute exacerbations had developed. This was followed two or three years later by well-marked emphysema. Besides cough, this disease occasioned shortness of breath, especially on going up stairs. This, however, never reached any important degree until the last weeks of his life, when he was often obliged to rest on the landings on going up to the third or fourth floor, and at times felt an oppression in the chest. After a few minutes' rest these attacks usually passed off. The stethoscopical examination, made by the son of the deceased, showed no disease, either in the heart or in the large vessels; only the above-mentioned chronic diseases of the lung were present. As the deceased, on the evening of May 1st, was returning from a visit, he felt a difficulty in walking in the somewhat high wind, and was unable to keep up with his companions, whom he asked to go on. He was several times seen standing outside shop-windows in Bredgade, probably in order to rest and regain strength. Shortly after his return home he felt severe pain in the region of the heart, and, as I was told afterward, a sudden feeling of something bursting in the left side of the chest. The pain increased, and the patient became uneasy and alarmed. When seen by Professor Frier, at ten o'clock P. M., he was pale and a little collapsed, the skin was cool and not perspiring, and the pulse slight, frequent, and irregular; he talked freely, and his respiration was not particularly accelerated. He moved about the room easily, undressed quickly and went to bed. Here he continued to complain of pain, which now included the sternal region and radiated out into the left arm to the fingers. He continually changed his position as if seeking relief, and used all his might to repress exclamations of pain. Attempts to give warm drinks, such as wine, camphor-drops, etc., failed, as they only produced nausea and sickness, which he himself repeatedly produced by thrusting his finger down his throat.

His mind was perfectly clear the whole time, and he even made jesting remarks on the inability of medical science to relieve his sufferings, for not only had mustard leaves, warm bottles, and incitantia, but also a considerable injection of morphine remained without effect. The pains began to decrease about midnight. After another injection of morphine he fell into a light, uneasy sleep.

The sickness did not return until after he had taken his coffee the next morning. Up to eight o'clock A. M. he felt so well that it was with difficulty he was persuaded to remain in bed and give up his morning lecture, and he gave directions as to his business letters. In the early morning he had thought out a thorough explanation of the functional disorders of the vagus and the sympathetic nerves from which he believed himself to be suffering, all of which he explained to his son, although unable to give a cause for them. Half an hour after his son had left him, his pulse being strong and his appearance decidedly improved, and a few minutes after he had spoken jokingly to those around him, he was heard at a moment when he was alone to utter a groan. He had fallen back cyanotic and unconscious, and a few minutes after he died. It must be added that, from the superficial examination which circumstances had allowed on the previous evening, no increased dullness of the heart had been discovered, but tumultuous action, with long, strong murmurs, which prevented the two heart-sounds from being heard or distinguished. That the patient was suffering from an affection of the heart, and that one which came under the category of angina pectoris, was clear to Professor Frier as soon as he had observed him a short time. It seemed improbable, however, that this attack should be the only one, and that the end was so near, as the pains had been diminished and rest obtained. The real cause of death was first discovered post mortem.

Autopsy, May 3, 1885, twenty-nine hours after death, made by Dr. Dahl.—Rigor well marked. Death suggillations all over the body. The panniculus adiposus well developed on the chest and abdomen. The two superior lobes of both lungs and the right middle one emphysematous and swollen, especially along their anterior edge. No *fluid*

in the pleural cavities. The mucous membrane of the bronchial tubes somewhat injected and covered with cohesive white mucus. The pericardial sac filled with a little more than a pint of dark fluid and clotted blood. Blood of similar appearance was seen to flow out of a fissure of the anterior left ventricular wall. This fissure was five centimetres long, and was parallel with and close to the septum. Its edges were lacerated. A similar but smaller fissure, one centimetre and a half in length, was seen along the first one, and united with it by a cross-fissure. Both extended through the subpericardial fatty tissue, which was infiltrated with blood and reached the muscular substance; this was perforated by several small fissures and holes, none of which were larger than that a probe could pass through. In the lower part of the fissure the probe entered a small cavity between the muscular and fatty layers filled with blood. The heart itself was flabby, with much subpericardial fat, especially at the apex, where it was more than one centimetre thick, while at the seat of the fissure the thickness was exactly one centimetre. In a few localities the pericardium was thickened and white. The heart was thirteen centimetres in length and in breadth. The apex was formed by both ventricles and a little rounded. The aortic valves were normal. The foramen ovale was open. The tricuspid orifice admitted three fingers, the mitral orifice four. The tricuspid and pulmonary valves were healthy. On the anterior mitral flap there was a large, white, thickened patch. The right ventricular wall was two millimetres thick, the muscular tissue being of a deep, dull, grayish-brown color. Toward the septum there was a limited yellow area extending somewhat in depth.

The cavity was enlarged, although the septum projected much. The left ventricular cavity was much enlarged—the wall in the thickest part 8 mm., at the apex 2 to 3 mm. The trabeculæ were flattened and not much developed. The muscular papillæ were of normal thickness, the muscular tissue being flabby and much softened, and its color like that of its right side; at several places yellow spots were seen through the endocardium. Toward the septum, at a point corresponding to the external fissure, there was a rectilinear fissure four centimetres long. It did not quite correspond to the external one, crossing it at an acute angle. The edges of this fissure were flattened; in the depth of it there were several small holes, corresponding to those described in the external fissure.

The surrounding tissue was very much softened, and infiltrated with dark blood. A fresh cut across the fissure and through the muscular layer showed this to be very thin—about 2 mm. close to the edge, and 5 mm. farther away. The aortic valves were somewhat thickened. In the tunica intima there were many white, fibroid patches, and similar ones were found in both coronary arteries. In the vertical branches of the left, just after its separation from the horizontal branch, was found a constriction which barely admitted the passage of a fine probe. Upon opening the artery here there was found a soft, yellowish white plug, adherent to the wall, where it covered a soft, atheromatous cavity formed in the thickened and partly calcareous intima, which was perforated in several places by small holes. From this place and down to the rupture the artery seemed healthy. A little below the plug a small branch went off; it could be followed to the spot of fatty degeneration in the right ventricle. Microscopical examination of the muscular tissue showed the fibers around the fissure atrophic and very fatty; there were no transverse striæ to be seen, and there was no increase of the interstitial fibrous tissue. The nuclei were normal; many of the fibers were broken by extravasation of blood. At other places, both of the right and left side, the transverse striæ were well marked, but everywhere there was more or less fatty degeneration. Other organs were not examined.

It seems probable that the plug which caused fatty degeneration of a part of the heart had developed during the last weeks before death, and had caused the shortness of breath and feeling of oppression. The rupture, the result of the degeneration, was probably observed by Professor Panum himself; but it seems to have gone slowly through the wall, from within outward, not causing at first any effusion of blood into the pericardial sac, but only irregularity of the action of the heart, pain, and nausea.

A New French Journal, entitled "La Normandie médicale," reaches us from Rouen. It is edited by M. Cerné and M. Gendron, with the collaboration of M. Duménil, of Rouen, M. Gibert, of Havre, M. Leudet, of Rouen, and M. Notta, of Lisieux. It is a semi-monthly octavo of sixteen pages.

The Health of San Francisco.—It appears by the Health Department's "Condensed Statement of Mortality" for October that the whole number of deaths reported was 432, of which 75 were from zymotic diseases, 92 from constitutional diseases, 195 from local diseases, 36 from developmental diseases, 28 from violence, and 6 from causes not ascertained.

The Johns Hopkins University.—The "Therapeutic Gazette" notices a rumor that Professor Matthew Hay, of Scotland, has accepted the chair of pharmacology.

The "Medical News" Visiting-List.—We have received a copy of the "Medical News" Visiting-List for the year 1886, and an examination of it leads us to think that it will be found exceedingly servicable. It has evidently been prepared with great care, and its mechanical get-up is pleasing. A very commendable feature is the thumb-index to the various departments.

THERAPEUTICAL NOTES.

Iodide of Sodium in the Treatment of Syphilis.—Arcari ("Gazz. med. ital. lombard."; "Med. Chron.") reports a number of cases of tertiary syphilis in which rapid improvement was due to the hypodermic use of this drug in quantities of about ten grains four or five times a day. He recommends the simultaneous use of thirty grains by the mouth, with only two daily injections, in cases where an organ is seriously threatened from syphilitic deposits.

The Stinging Nettle as a Hæmostatic.—Dr. C. J. Rothe ("Pharmac. Post"; "Therap. Gaz.") has experimented with the juice of the stinging nettle (*Urtica dioica*) as a hæmostatic. The leaves, flowers, and stalks of the young plant, gathered in the spring, are cut up fine, soaked for a week in sixty-per-cent. alcohol, and subjected to pressure. The liquid is filtered, when it is of a dark greenish-brown color, and has a spicy odor and taste. Applied on cotton, it rapidly arrests capillary hæmorrhage, and the clots formed are soft and tenacious.

Kava as a Remedy for Gonorrhœa.—Kava, a piperaceous plant indigenous to the Sandwich Islands, has been recommended by Dupuy and Gubler ("France méd."; "Dtsch. Med.-Ztg.") as a specific for gonorrhœa and leucorrhœa. It acts as a diuretic, diminishes the inflammation, and allays the pain. It has the advantages over copaiba of possessing an agreeable taste and of not disturbing the stomach. Gubler mentions a gum and a crystalline principle, kavaline, as the active constituents.

Cold Bandaging of the Leg in Insomnia.—According to the "British Medical Journal," Dr. von Gellhorn has found this practice very useful in cases of sleeplessness, especially from cerebral congestion. Sometimes he has found it necessary to reapply the bandage every three or four hours, as it dried. [It would be interesting to note what difference there is, if any, between the effects of this practice and those of the well-known device of plunging the feet into cold water.]

The Administration of Paraldehyde.—M. Lereboullet ("Gaz. hebdom. de méd. et de chir.") gives the following formula, proposed by M. Yvon:

Paraldehyde	150 grains;
Ninety-per-cent. alcohol	720 "
Syrup	900 "
Tincture of vanilla	30 "
Distilled water	450 "

A tablespoonful of this elixir contains fifteen grains of paraldehyde. Four soupspoonfuls should not be exceeded at a dose.

Phosphate of Bismuth.—Fredenat ("Giorn. farm. napol."; "Nouveaux remèdes") remarks upon the variable density of subnitrate of bismuth, and proposes the phosphate as a substitute, the latter being a stable salt. Its therapeutical properties are the same as those of the subnitrate, and it may be given in doses of thirty grains.

Essence of Peppermint as an Application to Burns.—"Nouveaux remèdes" quotes the "Australasian Chemist and Druggist" to the effect that essence of peppermint, painted on a burn, causes the pain to cease at once.

Lectures and Addresses.

A REVIEW OF THE LIFE OF LOUIS ELSBERG, M. D., AND OF THE ADVANCEMENT OF OUR KNOWLEDGE OF DISEASES OF THE THROAT DURING HIS PROFESSIONAL CAREER.*

BY MORRIS H. HENRY, M. A., M. D., LL. D.,
OFFICER OF THE ROYAL ORDER OF THE SAVIOR, OF GREECE; LATE SURGEON-IN-CHIEF OF THE NEW YORK STATE EMIGRANT HOSPITALS, ETC.

MR. PRESIDENT: By your favor I appear to-night to pay tribute to the memory of our late colleague, Louis Elsberg, who died at his home in this city on Thursday, February 19, 1885.

With one accord I know we shall agree that it was a useful and honorable life; and, now that it has passed away for ever, I would gather from it an account of the virtues it exemplified, that the example may serve for guidance in our own careers.

Louis Elsberg was born at Iserlohn, Prussia, April 2, 1836. He came, with his parents, to this country at the age of thirteen. His family settled in Philadelphia and the boy became a pupil in a public school. He subsequently went to the High School, from which he was graduated with honor in 1852. He then obtained a position as tutor in an academy at Winchester, Va., where he remained two years. He returned to Philadelphia and entered the Jefferson Medical College, and acquired a medical degree in 1857. Immediately following his graduation he came to New York, and for six months was resident physician at Mount Sinai Hospital. He then went abroad, where he remained for one year, and returned to this city, and at once began the practice of his profession. With Störk, Semeleder, Lewin, and Türck—all subsequently distinguished laryngoscopists—Elsberg formed one of the first class that received instruction under Czermak. Störk and Türck became professors in Vienna; Lewin filled a similar position in Berlin; Semeleder attained distinction in Mexico, under the Emperor Maximilian. Elsberg did his good work in New York, and became no less distinguished than the *confrères* of his early professional days. He was the first of this brilliant little class to succumb to the inevitable.

In 1861 he delivered a course of lectures at the University Medical College. The following year he established the first public clinic for diseases of the throat.

In 1864 he wrote his essay on "Laryngoscopical Surgery, Illustrated in the Treatment of Morbid Growths within the Larynx." It was the prize essay for which the American Medical Association awarded him the gold medal in 1865. The subject of this paper was, at the time, a new one. The account of his success in these operations marked a new era in intra-laryngeal surgery. In 1864 he published, under the title of "Laryngoscopic Medication," several papers which he had read before this Academy and other societies. In this publication he gave descriptions of many new instruments of his own invention—all well known to you. They included a new tongue-depressor, sponge-carrier, and concealed porte-caustique.

In January, 1874, he contributed a valuable article to the "American Journal of Syphilography and Dermatology" on "Syphilitic Membranoid Occlusion of the Rima Glottidis." He described eleven cases of the disease, and the operative treatment pursued for their relief. The results were satisfactory; and it must not be forgotten that they were obtained at the time when many able men were in doubt of the safety and feasibility of surgical interference in severe forms of laryngeal diseases.

In 1878 he read before the Academy of Sciences a treatise "On the Structure and other Characteristics of Colored Blood-Corpuscles," a paper which showed that he was not only well versed in biology and a good microscopist, but possessed and capable of a vast amount of original thought. In June of the same year (1878) he, with a few others, founded the American Laryngological Association, and he became its first president. At the first meeting he gave some account of the history of laryngology. His address, at the second meeting, on "Laryngological Instruction," was sent from Aix-la-Chapelle, where he had gone to regain his health.

In 1880 he began the quarterly publication of the "Archives of Laryngology," which was continued until 1884.

In 1882 he delivered the annual address—his subject being "Changes in Biological Doctrines during the Past Twenty-five Years"—before the Alumni Association of Jefferson Medical College. This, as he expressed it, was "the silver wedding of his class."

The rest, change of scene, and renewal of old and pleasant associations, on his last visit to Europe, proved of benefit to him. Shortly after his return he delivered a lecture on "The Throat and its Functions," at the hall of the Young Men's Christian Association. It was one of a series instituted by the New York Academy of Sciences. He contributed largely to the "Archives of Laryngology"—the publication of which has ceased. Among his contributions may be found "Angioma of the Larynx," "Neuroses of Sensation of the Pharynx and Larynx," "Paralysis of the Muscles of the Larynx," "Contributions to the Normal and Pathological Histology of the Cartilages of the Larynx," besides many other clinical reports of which I have no record.

His intense application to his work, on his return from Europe, was, no doubt, the cause of the return of his disease. His kidneys had been seriously impaired. So far as outward appearances extended he seemed to have recovered. For a long time, however, after the attack he was solicitous about himself, and referred guardedly to the future. In his last paper, read before the American Laryngological Association in May, 1884—on the subject of laryngeal spasm—he remarked: "I promise you that, *if I live*, I will prepare a more elaborate essay on the subject before our next annual meeting." The place that he filled at that meeting and before that association knew him no more for ever.

* Delivered before the New York Academy of Medicine, December 3, 1885.

Ten days before his death he contracted a severe cold, but persisted in the discharge of his regular duties. Pneumonia set in, and scarcely was it known by his friends that he was sick ere the report came of his death. A widow, a little daughter, and many relatives and sincere friends mourn his death. During the last few days of his illness he was attended by some of his devoted professional friends. He retained up to the period of his death the professorship of laryngology at Dartmouth College and at the Polyclinic of this city.

Just one year ago I had the honor of nominating him for the position of corresponding secretary of this Academy. He was, of course, elected, and I know he appreciated the honor it conferred. He had, for many years, devoted a portion of his time to the collection of materials as a basis for a more complete work on diseases of the throat. Had he been spared, he would have given us a satisfactory volume—a book that would have contained the results of investigations pursued in this country as well as of those of foreign sources.

Elsberg was the first, beyond any question, to demonstrate and teach, in public, in this country, the use and value of the laryngoscope in diagnosis and treatment. He leaves many disciples among his former pupils who will continue the same course of investigations. The best work of his life, however—the work that inures most to his fellow-men—was the diffusion of his knowledge and experience in such a way that all practitioners might render good special service to their clients.

I recall in detail the works of our late brother, for I think it well to place the results of his active and industrious life on the records of the Academy which he adorned.

The account of his contributions will serve as guides to those who succeed him. They will serve as a stimulus in the advancement of studies that are still in comparative infancy. The perfect assimilation of clinical facts for future clinical benefits requires time, and natural and trained capacity of no mean order. Sound clinical records—what I mean by sound records are truthful records—must ever be the great basis of advancement in the practice of our art. Elsberg was an astute clinical observer. The records of his observations show intelligence of the highest order and no ordinary manipulative skill in the management of his cases. His knowledge of music and of the functions of the voice made him the physician of many of the great singers who have visited our shores.

A statement was very recently made in this Academy, by one of its distinguished fellows, that in the year 1860 the use of the ophthalmoscope and the laryngoscope was unknown in the New York Hospital, regarded at that time, by universal consent, as the best endowed and the best equipped of all New York institutions for the relief of the sick and injured. This statement seems to us now a strange one. It establishes the fact that, at this time, the use and value of the laryngoscope were scarcely known in New York. In the year 1858 I devoted a portion of my time to the study of the uses of these instruments in the treatment of specific diseases. I was "but a student." I mention this because when I subsequently—in 1864—first met the subject of this memoir, and in the course of conversation alluded to my own early experiences in the use of these instruments, it assisted in forming an attachment—a bond of sympathy in the study of congenial pursuits that was never impaired, never canceled.

It was during my early investigations of diseases of the throat with the laryngeal mirror that I first thought of the concentration of light by the simple means of a large plano-convex lens mounted in such a way that it could be used with any form of artificial light. By the advice of Elsberg I published an account of my method in the "American Medical Times," June, 1864, edited by the present distinguished chairman of the Section of Surgery of this Academy. This instrument is, I think, still deserving of attention. It is inexpensive, easy of application, and will answer perfectly all the demands of the routine range of diseases of the throat, larynx, and nasal passages. This same instrument has passed under other names since the date of publication I have just mentioned.

No allusion to the subject of the nature and treatment of diseases of the throat and air-passages in this country would be complete without reference to the accomplishments of Horace Green. He was the first and only specialist up to the period of Elsberg's advent in New York. May I not pause to say a few words in memory of that distinguished Fellow of this Academy who gained celebrity by his thorough knowledge of the science of medicine and the skill he displayed in the practice of his art? Without any disparagement of those who are now engaged in the same department of medicine, and although a quarter of a century has passed since he added luster to this Academy, that luster has never been dimmed by later work. It is possible that I may not do full justice to those who have followed him, but I have searched in vain through the transactions of this Academy to find his peer in contributions to diseases of the throat and air-passages. He was, like Trousseau, a teacher of the practice of medicine, and with that combined the elements of an admirable physician. His knowledge of the art of medicine was of service to him in the more limited range of practice to which he devoted the best years of his life. I remember him well as a teacher. He was a good one. His statements were reliable. In his controversies with Trousseau—when the illustrious Frenchman disputed his ability to pass the sponge into the trachea for topical medication—Green bore himself with dignity and ability. It would be well for the present generation to refer now and then to the works of their predecessors. While there was, perhaps, not less strife in the race for fame and fortune, there was, at least, less sensationalism and less seeking for secular newspaper notoriety; the genius for popular secular advertisements may have been born at the period of which I speak, but its full growth has only been attained within the past few years. Green, like other specialists of great attainments and distinction, knew well and taught the necessity of natural qualifications, as well as of a sound general education, as the basis of a successful (scientific) career in medicine. There is still lingering a theory that with a charter and a heavy dose

of teachers you can take anybody, from any trade or any sphere, and turn him out a physician or a surgeon—usually both—after "two full courses of lectures." Green was one of the teachers who did not share in this heresy. He knew that to make a good doctor you must have a first-rate man when you begin. He was the founder of a college, and, in mapping out the course of instruction for its alumni, he bore in mind the essential qualities of his teachers. In this, too, he was in advance of his time. He knew that "you can not create teachers as if they were light-infantry men, who can be manufactured out of clowns by three months' drill." He advocated his views more than thirty-five years ago. Twenty years have elapsed since he passed into eternal sleep. The purpose he toiled to serve is still in advance of the practice of the day. He was singularly successful in the choice of many of his colleagues. Many of the most distinguished have followed him to their last home. Among them were Conant, Childs, Cox, Stiles, and Peaslee. If I may single out for mention one of all others of that "old Faculty" who has been spared to us and who has won great distinction—you, Mr. President, must know to whom I refer—your revered predecessor, Fordyce Barker. Before ending this reference to Horace Green, let me recall to your mind the purity of his conduct and the nobility of his bearing in his last scientific struggle in this Academy when called upon, in 1859, by John Watson, for information in the case of, and as to the cause of, the death of the late Stephen Whitney. That extraordinary attack left no blemish on the character or skill of Green; but it left an insidious impress that hastened his death. His principal opponents, also distinguished in this Academy—I forbear to mention their names—have also, ripe in years and honors, passed away. I refer to these facts, for they serve as the best text for a lesson of forbearance and the cultivation of an honest, kindly intercourse among us in all our meetings.

During that period of excitement pending the discussion of "the code question" Elsberg could not be otherwise than thoughtful and liberal. He was gentle in the expression of his opinions. He was intense in his convictions. He never faltered in the discharge of an obligation or duty when once assured of its correctness and the probability of its serving a good purpose. While he was registered—if I may use the term—as a "new-code man," and I on the other side of the question, there was, in reality, no difference whatever in the substance of our views. A calm discussion of the questions at issue proved us in unison. Might not more forbearance have prevented the strife that disorganized associations and dissevered friendships of a lifetime? A calm, retrospective review of the field of battle tells again the sad tale of "what might have been" had wiser counsels prevailed. Elsberg shared the common feeling of all educated, thoughtful, honorable practitioners of medicine, that there should be no necessity of a code beyond that unwritten code of ethics that should govern the conduct of gentlemen in every sphere of life. He knew of, and fully appreciated, the difficulties of any enforcement of a statutory enactment or a professional mandate against persons devoid of honor and unworthy of fellowship in a liberal profession. He knew also that the attainment of this boon—a difficult one—could only be reached by the imperative demand of the profession at large that the mills should be stopped, and that there should be no more enlistments of ill-informed, improper persons to the ranks of our sacred calling. He knew also that you can neither teach nor enforce virtue by resolutions or text-books. He knew, Mr. President, as you and I know—no one better than yourself—that the enlightened men of this country—the class that have shed most luster, that have attained most honorable distinction, whether now rated (by irresponsible and illiberal factions) as new- or old-code adherents—are of one accord. The admission of the necessity of a special code—it is useless to deny it—is virtually an admission that the rank and file of the profession in this land is inferior, in moral integrity, to that of all other countries. I, sir, am unwilling to admit of any basis for any such conclusions.

There is seldom any romance associated with the lives of the serious workmen in science. The element of romance seems to be reserved to the credit of *soi-disant* followers that are but spurious imitations of the genuine men. Elsberg's career was a serious one. He knew no rest from toil, or thought of the work to which he devoted his life. He paid early the penalty of his incessant labors in a depreciation of his constitution that with gentler, less ardent enthusiasm, might have spared him to us many more years. He yielded to the natural characteristics of his race, the race of romance and reality. He belonged to that "chosen people" that conquered the empires of the East long before the dawn of the Christian era; to that race that has survived unparalleled persecutions from post-biblical periods down to the dark days of the Inquisition.

From one of his people—descended of those born on Latin soil, the same that gave birth to the Disraelis, Montefiore, Jessel, Aguilar, and Castelar, brilliant in art, literature, law, statesmanship, and humanity, not less dazzling to science—we are indebted for the first account, by the use of the laryngoscope, of the action of the vocal cords during inspiration and vocalization; important observations on the production of sound in the larynx; and valuable reflections on the formation of the chest. The story of the investigations of Manuel Garcia, who published, in the year 1855, in the proceedings of the Royal Society of England, his physiological observations on the human voice, is too well known to you to call for further reference on this occasion.

If the utility and value of a life be measured by the advantages which accrue from the love, devotion, and labors of those ever ready to sacrifice self in ministering to the ills of poor suffering humanity, surely no one will now deny a worthy site to the memory of our late friend and Fellow of this Academy.

The Comparative Action of Alcohol and Coffee.—W. B. Lewis ("Jour. of Mental Sci."; "Arch. de neurologie") gives a detailed account of certain experimental investigations of the action of these two agents. While alcohol increases the production of heat, it really lowers the bodily temperature by virtue of exaggerated radiation. Caffeine, however, preserves the heat, and thus, if given in conjunction with alcohol, tends to restrain the lowering of temperature that would otherwise be caused by the latter.

Original Communications.

JOINT DISEASES;
TREATMENT BY REST AND FIXATION.*

By De F. WILLARD, M. D., Philadelphia,

SURGEON TO THE PRESBYTERIAN HOSPITAL; LECTURER ON ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

The application of rest as a principle in the treatment of joint disease, although very generally accepted, is yet frequently employed only as an adjuvant to other measures of relief, while its proper position is in the first rank, and all other means are but subsidiary.

The principle is capable of wide application in medicine. Splints—rest-producers—are applied in fractures and in wounds to limit inflammation. Inflammations of the pleura, liver, intestines, or peritonæum are best controlled by absolute recumbency. In joint inflammations, quietude, unaided and alone, is capable of effecting more in averting and subduing a developing disease than iodine, blisters, heat, cold, the cautery, *et id omne genus*. These measures, powerless in themselves, are, however, useful as supplemental treatment; but no surgeon is justified in trusting to their power when dealing with a disease which is so prone to develop the most serious results if neglected. As soon should he trifle with a bleeding femoral artery or a post-partum hæmorrhage. In osteitic cases, especially, the evil tendency is so strong that no time can be lost.

Those who advocate the "motion-without-friction" cure assert that motion is the normal condition of a joint, which statement, while true as regards normal articulations, is no more applicable to diseased ones than to inflamed muscles or other tissues.

Friction is constant during walking. I took occasion to count my steps for a single square to-day. Ninety times each of the joint surfaces of my lower limbs was concussed between the stone pavements and the superincumbent weight of my body in two minutes, or nine hundred times in a walk of a mile. If inflamed or roughened, the effect of such friction would be just as disastrous as the rubbing of a hard substance upon an irritated external sore or pimple, and the results, though temporarily concealed, would be none the less destructive. Nature evinces her aversion to motion by producing the most perfect rest which she is able to accomplish unaided. Muscular rigidity is the first and most common *avant-coureur* of danger.

When I speak of rest for a joint I do not mean that it should be that form of confinement to the house that allows the child to run up stairs, and play at games which will be more severe upon his articulation than walking. If the affected member is the lower limb, it should under no circumstances be placed upon the floor, and, until pain and all signs of acute inflammation have subsided, the recumbent position should be unceasingly maintained. If starting or spasmodic pains are present, weight and pulley extension should be employed, and fixation enforced until relief is secured. Then, and only then, should crutches and apparatus be used. By the careful enforcement of such a course, synovitis, if taken early, can be aborted, and articular osteitis so modified that its evil effects will be reduced to a minimum. Surely if such results are compared with the terrible consequences which follow procrastination, or temporization with ineffective counter-irritative measures; the slight restraint put upon a child at a period of life when a few months or even years are of slight importance can not be considered for a moment.

The abortion of articular disease is considered impossible by some surgeons, but cases of traumatic origin can within the first ten days be easily checked. The skeptical maintain that such a case is not one of true joint disease. It certainly is not articular osteitis; but a flame is as much a fire, save in degree, when first started, as when it has become a conflagration, and every suppurating articulation had a stage when it was but a tiny spot of irritation. One week of proper early treatment is more efficient than months of later work. The one objection to absolute rest can be obviated by rigid rules in regard to the admission of fresh air to the room. Windows should never be closed night or day, as warmth can be secured by additional coverings.

My practice is about as follows: For use by day a narrow platform is constructed of light boards, with a handle at each end, and on it is placed a firm hair mattress. To one end is attached a grooved pulley-wheel, over which plays the extension cord, with from two to ten pounds attached —comfort regulating the weight. This bed can easily be picked up by two persons and laid upon rests beneath the trees or on the porch, or it can be placed and locked upon a child's express-wagon, or, better, upon a frame wagon with easy springs. If removal is painful, the entire fixture can be laid upon the couch at night, but ordinarily the sliding upon a bed is not harmful, provided extension is maintained.

By this method an abundance of fresh air and exercise can be secured with little expense, and the patient will be contented and happy. When the starting pains are severe, and especially when the patient is intractable, the addition of sand-bags, or, better, of a Desault long splint, will be of service for the first ten days. This splint, covered with muslin or bandages, can be retained in position by an underwaist, to which it can be fastened by safety-pins. A rope stretched above from head to foot, together with a few toys and bent wires, will assist in sports and remove the great temptation to sitting up. After restlessness has ceased, the side-splint can be removed, and the freedom of sitting upright for an hour when weary does no injury, provided twisting is avoided. Should these means fail to relieve pain, the direction of extension should be changed and a plaster-of-Paris, leather, felt, or binder's-board splint be fitted. Wire gauze also has been applied, and constitutes an excellent dressing. It makes but slight difference how fixation is accomplished, and each surgeon will have his own particular method. I am speaking now of uncomplicated cases in their early stages, having in mind chiefly knee and hip inflammations.

If extension is commenced in the line of the deformity,

* Read, by invitation, before the Lehigh Valley Medical Association, August 19, 1885.

a change for the better can soon be accomplished until gradually a more normal position can be secured. In many cases a cautious surgeon can gain considerable time by straightening the limb during anæsthesia, but such a procedure requires the utmost caution lest new inflammation be excited. Tenotomy and aspiration are often advantageous.

I have no doubt that strict confinement in bed would be sufficient without extension in slight cases, but it is difficult to prevent a child from quietly slipping off the couch unless some decided impediment is offered. The method may be temporarily adopted, however, where the other treatment is viewed with disfavor, since, at the end of a week, so great is the mitigating power of time, the parents will acquiesce in a restraint which at first seemed unwarrantable to them. Counter-irritants can be used if desired, since they exert a good influence at least upon the attendants. All hygienic, supporting, and constitutional measures should be most carefully watched.

The time of confinement varies according to the conditions. In the hip much will depend upon the synovitic or osteitic character of the disease. If synovial, slight, and traumatic, a few weeks may be sufficient; but, if osseous in origin, several months should elapse after all cessation of pain before the crutches should be permitted. Night extension is often beneficial, even many months later. A simple over-gaiter is then the best foot attachment. If the knee is at fault, extension is rarely required for any length of time, simple fixation with rest being all-sufficient. These conditions are much more readily secured than at the higher articulation. It is better for the patient, however, to remain in bed during the acute stage, since more perfect quietude can be obtained. If the inflammation is violent, not only must fixation be secured by the adaptation of a posterior splint of wood, leather, felt, binder's board, tin, etc., but ice should be steadily applied in a rubber bag, or coil, or bladder. The action of this powerful agent upon the capillaries may be enhanced by covering the skin with lint wet with a saturated solution of sugar of lead, made anodyne in its properties by the addition of opium. Leeches also may be of service in an acute traumatic case.

In osteitic cases, however, the chief reliance must be upon rest, a condition which is most thoroughly secured by fixing the limb in the most comfortable position by gypsum or other material. If slight deformity with effusion has occurred, the procedures before alluded to must be practiced. Sponge-pressure or a close-fitting rubber bandage is of great service. If there is a tendency to posterior displacement of the tibia, extension must be made in two directions: one weight drawing downward, while another band is placed around the upper third of the leg, at right angles to the axis, and through a pulley in the ceiling the limb is suspended in such manner that forward traction is continuous upon the head of the tibia. Should this fail, tenotomy of the ham-strings will frequently hasten relief; but when displacement is great, of course, ligaments are destroyed, and even if restoration is accomplished it can not be maintained without absolute fixation.

In knee arthritis which is osseous in its origin, or when the joint is undergoing pulpy or fungous degeneration, when good position has been secured, or when ankylosis is to be desired, the complete incasement of thigh and leg is better than posterior splints. The enveloping ones of sole-leather, which can be laced and made removable, or the lighter ones, of partially tanned hide, are, however, very serviceable in the later stages. It is, of course, understood that all these appliances are intended to promote as perfect rest as possible, and that walking without crutches is absolutely to be forbidden, the injunction being that the foot shall *never* be brought to the ground. Without this restraint many steps about the house will be taken and great injury inflicted by friction. A high shoe upon the sound foot prevents the striking of the toe, and removes the temptation to walk.

Slight injuries or trifling synovitis may, of course, recover by counter-irritation, cold, etc., even though rest be but partial; yet even these cases are not without risk, and should receive the closest attention.

Osteitic cases, the old "white swellings," demand, from their inception, the most rigid enforcement of the principle of complete fixation, while every available constitutional health promoter is brought actively into service.

In hip disease, after all pain has ceased for months, and earlier if the general health demands, some form of apparatus should be applied to prevent joint motion and yet permit the patient to move about on crutches, and with a high shoe on the sound foot.

In this department every surgeon has his particular modification, and believes that it alone is capable of giving good results. While pleading partially guilty of the same weakness, I am yet able to see merits in all fixation splints. As for the so-called extension appliances, although I have seen nearly all of them in service, I can not imagine that they exert any separation of articular surfaces. By adhesive-plaster and bandage-pressure their beneficial action is, however, probably exerted in controlling muscular action, and thus giving a certain amount of rest, fixation, and protection, particularly in those appliances in which hip-joint motion is transferred above the pelvis. I employ horizontal extension, not with any idea of pulling the bone from its socket, but simply to relieve muscular spasm, give quietude, and reduce deformity.

I am compelled also to differ with many skilled surgeons, who believe that the perineal straps and ischiatic rests are capable of acting as pelvic crutches, and thus doing away with axillary ones. The tissues covering the pubic rami are thin and the skin is sensitive, and, as I have always encountered these appliances, the patients either could not endure the pressure, or, as more frequently happened, the straps, except for an hour after the physician's visit, were so loose that the weight was borne upon the articulation, and relapse has been the result. Even when most perfectly adapted, the jar upon the hip is far greater at each step than is received during axillary locomotion, and the liberation of the arm from restraint is not sufficiently compensatory for this harmful action.

Only a few weeks have elapsed since I saw a most lamentable instance of this effect, although the splint was in most careful hands and was one of the best of its kind.

Hutchinson's plan of permitting the patient to go about with crutches and high shoe, without splint, is a method to which we are often obliged to resort among poor patients, but it compels the hip-guarding muscles to remain in a vigilant state during the entire day, in consequence of which increased congestion starting pains will continue throughout the night in spite of extension.

The surgeons who strive most earnestly to obtain a cure with motion are the ones who are obliged to perform the most resections. Decide upon the instrument that will give the most absolute rest, and you will make the best cure. The indications are to fix the joint, protect it from injury, maintain proper position, and yet be light and comfortable. Innumerable methods have been tried in order to secure these results at slight expense. Binder's board, leather, plaster (even when stiffened with tin strips)—all fail in the case of active boys, owing to the long leverage and great strength of the thigh muscles. Leather answers best, but in adults so large a piece is required that the expense is considerable. Vance's splint is a good form. Thomas's posterior bar and Agnew's modification answer a good purpose, but are open to the objection that sitting is impossible in a proper position. To accomplish it, therefore, the boy soon learns to twist his body, and also his hip, thus giving the joint each time a decided strain. This appliance, however, has many advantages which are not to be obtained in other forms, and is especially of service in dispensary and country work. Simple bars of cast-steel, one, two, or three sixteenths of an inch in thickness, and from one half to one inch in width, can be easily cut to proper length and bent by wrenches or in a vise by any practitioner, so as roughly to fit the posterior part of the body from the thorax to the calf. Two tin strips to encircle the body, and one each for the thigh and leg, can be soldered or riveted to this upright, and, when all is fixed in position by gypsum bandages, a very rigid support is obtained. The encircling bands can be made of steel, which, when covered with leather and provided with buckles and straps, give a removable apparatus that, though less effective, is more comfortable and cleanly.

Any rigid material is as good as plaster. One great drawback to gypsum in its fixation uses has been the uncleanliness and annoyance of making the bandages. This is now avoided, since the instrument-makers are furnishing them for $2.50 a dozen, which is much cheaper than to make them one's self. The crinoline should always be open-meshed, and the plaster fresh. Oven-heating will often be of service. Muslin bandages will not retain sufficient gypsum. In order to secure the fixation of the joint and yet permit the sitting posture without the necessary twist produced by Agnew's or other instruments, I employ a lock joint, which is perfectly rigid except at the moment of sitting, when the simple lifting of a bolt from a mortise permits flexion, while at the same time no lateral or rotary motion is possible. On rising, the lock is easily managed under either male or female clothing, and the articulation is protected from blows on all sides. The joint is attached to Y-shaped arms, riveted to thigh and body enveloping bands of leather or felt. The trunk section must extend as high as to the lower angles of the scapulæ so as to embrace the thorax. For accurate adaptation, a plaster cast of body and thigh should first be taken; but approximation may be secured by leather cut to measure, then wet and fitted to the body. Russian felt can also be employed, as it is readily molded when heated and sets quickly. Lace hooks complete the splint and render it removable at will.

Objection has been raised to my apparatus, that it permits motion; but experience shows that the simple temporary flexion movement is far less injurious than the twist necessitated by other fixation splints, since it is impossible to restrict patients to standing and lying. Chance's splint, like my own, embraces the thorax—a condition which I consider essential, since pelvic bands permit compensatory motion too near the hip. Crutches, and a high shoe on the sound foot, are always used with this appliance. Its total weight for a child need not exceed one half pound. While not an extension splint, its action is to relieve the articular surfaces by controlling muscular action and by distributing the pressure over a large area of surface, just as a plaster or leather jacket relieves the vertebræ by transferring weight to the material through skin contact. The great support given to the hip by this splint is markedly evidenced in its employment for ununited intra-capsular fracture and in paralysis. If we prefer extension apparatus, we have a choice among many varieties—Taylor's, Sayre's, Gibney's, Judson's, Bauer's, Stillman's, and a score of others. I have already stated my objections to them. Each has its advocates, and doubtless each surgeon can report good cures; but it is not a particular splint which cures hip disease. The good progress of a case depends upon the fidelity and care which both surgeon, nurse, and patient give to the proper guarding of the joint, to the carrying out of all the little details of treatment, to the strict obedience to the command of non-use of the limb, to the persistence of all these through the years of first, second, and third stages. Each case will test the ingenuity of the surgeon and the patience of the sufferer.

I have purposely omitted the treatment of the suppuration stage of the separate joint diseases, with all the various complications, since their discussion would lead us on to excision and the later stages, which our space will not allow; but the principle of rest is at all times applicable and beneficial. I can not forbear, however, to insert one word in regard to diagnosis. Whenever muscular rigidity is present about any articulation, too much attention can not be given to its significance, due as it is to the fact that neighboring joints and muscles are supplied by the same sets of nerves, and irritation of an articular branch fortunately displays the warning signals—*muscular fixation* and *starting pains.*

At the ankle and foot immobility can be secured by wood, binder's board, felt, silicate of sodium, starch, oxide of zinc and glue, gypsum, or any other convenient means, rest of the inflamed surfaces being the result to be obtained. The means of securing this will vary with the joint affected, whether ankle, tarsal, metatarsal, or phalangeal. The principle is applicable to all stages, and, as caries of the bones almost always co-exists, it will be found that gypsum will answer best, since it can be easily windowed, and, if varnished, is quite non-absorbent of pus. A tightly fitting

stocking is the best under-dressing. The more absolutely rest is insured, the less will be the inflammation and the smaller will be the suppurative results.

If the case is of long continuance, a molded leather splint which can be laced is of advantage. Walking without crutches is never allowable. Long-continued suppuration is the rule, and free drainage must be established. Gouging, excision, and amputation are, unfortunately, often required in the later stages.

The primary fixation position in this articulation, as in all others, should be the one which gives greatest comfort.

Extension knee and ankle splints are in no wise superior to fixation ones, and are far less comfortable. They can not safely be used without crutches, and are useful only so far as they give quietude to the joint, a result which can be secured with much greater ease and benefit to the patient by other means, at one tenth the trouble and expense.

When strumous inflammation attacks the sterno- or acromio-clavicular articulations, the osseous structures are almost sure to be primarily or secondarily affected. In a case which came under my care last June, a few weeks sufficed to cause destruction of the ligaments and head of the bone. Tissue-death continuing, the anterior two thirds of the clavicle perished, and, protruding through an integumentary opening, were easily removed.

To retain these two articulations in a position of quietude, the same means should be adopted as are employed in shoulder disease.

At the shoulder we have a joint which, though but seldom the subject of articular osteitis, yet when attacked is, from the movable character of the scapula, so difficult to keep at rest that ankylosis, suppuration, and bone-death are very frequent results. If "extension with motion" was the true theory of treatment, we ought here to have most admirable results, since the weight of the extremity makes an excellent extending force; but, on the contrary, we are usually doomed to disappointment.

To produce partial rest, the arm should be bound to the side of the body, borated or salicylated cotton being interposed between the two skin surfaces. If the patient is young, a large body-waist or broad muslin strip is better than bandages. The shoulder can be still left exposed for counter-irritation, if desirable. Should maceration of integument take place in the axilla, a sling may be worn for a few days, with a shoulder-cap of binder's board.

At the elbow it is not difficult to maintain rest, but, as the majority of cases of arthritis met with at this joint are strumous, and commence in the humerus, extensive suppuration is the rule. A permanent splint is better than one that is removable, and nothing answers better than plaster of Paris. The angle of fixation should at first be the one that will relieve pain, but changed from time to time so as to give a good position in case of ankylosis, the hand being placed slightly in pronation, so as to avoid the tendency of the head of the radius to displacement as disorganization advances. If the swelling diminishes, the incasement can be slit and tightened, or a new one applied. Traps can be cut for counter-irritation or to give exit to discharges. The aspirator should be used early, sponge or elastic pressure being afterward applied. Suppuration from the humeral condyles is common, and excision is frequently demanded. A laced leather splint is often convenient.

The wrist joint, like the ankle, is subject to a strumous form of inflammation which may extend to the bones, or, as is perhaps more frequently the case, an osteitis may involve the joint and pass to all the carpal bones and articulations. To apply the principle of rest, we have here, first, to tightly wrap the wrist and hand with an adhesive-plaster bandage, which exerts pressure and tends to prevent the posterior displacement of the carpus which is so common when the dorsal ligaments give way. Over this should be applied a gypsum bandage, the hand being held during the hardening process midway between supination and pronation. This dressing answers much better than a palmar splint, and windows can be cut as required. If one prefers any other form of immovable dressing, it may answer just as well; but, if salt is added to the water in which the bandages have been soaked, the quickness of setting is decidedly in favor of plaster over any other material. Shingles and stiff paper are, of course, more constantly at hand, but require careful subsequent attention and are not nearly so certain in their fixation powers, since bandages will constantly loosen. In chronic cases a removable leather splint is useful.

The caries of bones and the fungous degeneration of the synovial membranes very frequently demand partial or complete excision or amputation. Unfortunately, surgical interference is frequently followed by increased bone-death, as is also the case in the tarsus.

To sum up in outline:

1. Rest subdues joint inflammation more effectually than all other means combined, often aborting, always lessening, an impending process. Its employment is indicated by nature; its beneficial influence is seen in every domain of medicine; in theory it is rational, in practice it fully proves its power.

2. The more perfect the rest, the greater will be the diminution of pressure, friction, tension, and inflammation, and the less will be the resultant ankylosis and suppuration.

3. The means for securing rest and fixation are exceedingly simple, and can be applied by every intelligent practitioner.

4. Counter-irritation is but of secondary importance.

5. In inflammations of the sterno-clavicular, acromio-clavicular, and scapulo-humeral articulations the arm should be fastened to the body, which takes the place of a splint.

In elbow disease the member should be immovably fixed in a semi-flexed or in an extended position; pressure, aspiration, puncture, drainage, excision, etc., to be employed as necessary.

In the wrist and hand articulations the same principle is to be enforced, long-continued rest being necessary. Early exit of purulent accumulations must be secured antiseptically by the bistoury, and the progress of caries carefully watched, the surgeon interfering only when nature is unable to properly accomplish separation or health fails.

In the ankle and foot the same will hold true, fixation by plaster or other rigid material being complete and per-

manent. Locomotion for even one step without the aid of crutches should be positively forbidden—an injunction which is equally applicable to diseases of the knee and hip.

At the knee, the question of counter-irritation, immobilization, or rest in bed with extension, will depend largely upon the amount of traumatism and the existence or absence of muscular rigidity. When nature indicates by the last-mentioned symptom that motion is harmful, delay in enforcing one of the latter measures is criminally negligent.

Serous effusion should be aspirated, pus evacuated antiseptically, free drainage maintained, and excision practiced as soon as it is decided that destruction has occurred.

Permanent rest and fixation, with the use of crutches, are far better than any form of extension that can be applied in the upright position.

In hip disease, horizontal extension with fixation answers best for the acute stage. Three months after the cessation of pain, if deformity has been largely reduced, the erect position may be assumed, provided the joint is put at rest by a fixation apparatus and the high shoe and crutches are used.

1818 Chestnut Street, Philadelphia.

THE ANNUAL AND SEASONAL CLIMATIC MAPS OF THE UNITED STATES;

WITH A RULE FOR THE EVEN DIVISION OF CLIMATE,

BASED UPON THE AVERAGE OF THE COMBINED ATMOSPHERIC HUMIDITIES IN THE UNITED STATES.*

By CHARLES DENISON, M. D.,
DENVER, COL.

(*Concluded from page 603.*)

The rule of moisture and dryness mentioned above is stated as follows: First find for the given time and place the per cent. of relative humidity and cloudiness, and the absolute humidity in tenths of a grain of vapor to the cubic foot of air. Then compute the difference between one third of these three and the standard number given opposite the proper temperature (of the given place) in the "Rating Table," and the result, plus or minus, will show the relation of the given climate to the average for the United States. An excess of six belongs to *moderate moisture*, and over six to *extreme moisture*, while a deficiency of six locates a place in *moderate dryness*, and over six in *extreme dryness*. On the map each of these four divisions is divided into halves, thus giving eight even divisions of the whole climate. The gradations toward the extreme of moisture or extreme of dryness are thus easily seen as the colors change from the mean of climate, which is the dividing-line between the blue and red shades.

It is claimed for this mean of climate for the United States that it is only approximately correct, because the colors of the seasonal charts do not represent a period longer than one year (1883), and because the density of observation stations in the United States is very unequal. An effort was made to counteract this latter circumstance by taking the average relative humidity of places representing about an equal area along parallels of latitude. The averages thus obtained, of 67 per cent. of saturation for relative humidity and 44½ for cloudiness, were considered by the Signal Service authorities in Washington to be about as nearly correct as could be obtained. A little too much of the country may be apportioned to the blue shades, yet, if that is the case, it makes no difference with the extremes of either moisture or dryness. Here it should be noted that the excesses, from the annual average for the whole country, on the side of dryness (red) are much more than on the side of moisture (blue). For instance, Red Bluff, California, in summer—with a cloudiness of 13 per cent., a relative humidity of 34 per cent., and an absolute humidity of 3·7 grains to the cubic foot of air, giving a mean of 28 to compare with the usual mean (62·7) in the table for Red Bluff's temperature, 82°—gives an excess on the side of dryness of 23 above the extreme of dryness, while Spokane Falls and Port Huron, Mich., two of the moistest localities in winter, give only 4 excess above the extreme of moisture. This less fluctuation on the moist side of the average of climate is in perfect accord with the greater variability of climate according to the dryness of the air. These facts, and the proofs the author presented in his last year's report, that equability goes with warmth and moisture of atmosphere, should always make us suspicious when equability is claimed for dry, cool places, or when great dryness of atmosphere is alleged for warm, equable places.

The other features of the seasonal charts are easily understood—*i. e.*, isotherms, wind-arrows, and seasonal tables—by referring to the descriptions already given and simply substituting *seasonal averages* for *annual means*.

For instance, the isotherms represent belts of country of the same seasonal average of temperature. The same winds averaged for seasons are *prevailing*, *rain-bearing*, and *pleasant-weather producing;* but, instead of representing regions, as on the annual map, they answer for each signal station near which they are placed. In the border tables the *comparative windiness* of stations is worked out from the seasonal averages of miles the wind travels a month, which latter are likewise given at the sides of the charts. Besides the seasonal averages of cloudiness, relative and absolute humidities, precipitation, daily and monthly ranges, and the 1883 seasonal averages of temperature which are given below the seasonal charts, the establishment and elevation of stations, the annual cloudiness, annual temperatures, and mean annuals of maximum and minimum temperatures are given on the sides.

The basis map of the seasonal charts contains all the signal stations, State capitals, principal cities, health stations, and all the thermal and mineral springs of note, including many as yet unnamed, and comprising the most complete list of such springs extant.

The absolute humidity table, given on the chart for autumn (see Gulf of Mexico), is added for the convenience of those who may wish to compute the standing of places not rated on the charts, while the presence of the "Rating Table" and "Rule of Moisture and Dryness" on the chart for summer gives opportunity for any one to make such computations, or to prove the color shades as given for any signal station.

It is to be explained that barometrieal records, atmospheric eleetrieity and ozone are not given for the following reasons: The uncertainty incident to the fickleness of barometrical readings, with the necessity to reduce them to a sea-level standard, is not thought to be warranted by any good that would result; while atmospheric elcetricity and ozone are not yet estimated, if at all, with sufficient degree of accuracy to allow of their use.

The principal feature of these seasonal charts is the illustration of the method of dividing the climate into even portions, based upon the average of atmospheric humidities for the year. If this standard of evenly subdividing the climate of our own country shall be accepted as the rule by the Climatologieal Association until a better is submitted, the author will feel amply paid for his labor in working it out and presenting it to the medical profession.

DISCUSSION.

The PRESIDENT had received the maps three or four months before, and had spent some time, but perhaps not sufficient to express an opinion, in examining them. It seemed to him that Dr. Denison had endeavored to put too much on the maps, and they were confusing, to say the least, on that account. That was the only criticism which he had to make with regard to them. How reliable the observations made were, he supposed was only to be determined by the accuracy of the signal stations observations. With regard to the final deductions which the author made, he thought, as stated in his address, that humidity which was prejudicial to phthisical patients had more to do with the soil than with the general atmospheric condition, and therefore it would be necessary to know more of the soil of the different localities that were supposed to be specially favorable for phthisical patients before he should be willing to express an opinion. He believed that all of the gentlemen who had been the most correct in the matter of climate, starting with the observations of Dr. Bowditch in 1862, agreed that dampness of the locality due to the condition of the soil played an important part in the development of phthisis. It was not the amount of rain-fall, nor the amount of relative humidity, but the want of free drainage in the soil. Dr. Bowditch, in his address before the Massachusetts State Medical Society, had dwelt upon this point very strongly and very clearly. When the speaker first went into the Adirondack region as an invalid it seemed to him that everything was against its being a suitable place for phthisical patients so far as humidity, changes of temperature, and all that was concerned; but the results had proved that it was a good place for phthisis—certainly in the earlier stages, and the principal reason was the condition of the soil. There was no clay in the Adirondack region, and everywhere there was quick drainage.

Dr. A. N. BELL remarked that the maps which Dr. Denison had prepared to show the relative moisture and dryness in different parts of the United States, with a view to enabling physicians to decide where to send their phthisical patients, went far to counteract the position which Dr. Denison started out with, that dryness was the essential element in the cure of phthisis. Studying these maps, and the reports on which they were based, we found some curious facts. In Colorado, for example, the ratio of mortality from consumption to the mortality from all causes varied only a small fraction of one per cent. from that of Florida, Mississippi, and Louisiana, exclusive of New Orleans, where there were just reasons why the mortality from phthisis should be excessive. It was considerably higher than in Texas, which also had a damp climate. What the president had said with regard to the Adirondack region had an equal bearing on the subject. Everybody knew that forests were the storehouses of moisture, and, so far as we could go in measuring these climates, they were exceedingly damp, and for manifest reasons—not only because of the large amount of rain-fall, but also because the leaves interfered with evaporation. It had also been shown that there was something besides heat, as well as besides relative dryness, which had an important influence on the consumptive. We might refer to the statistics of the navy. It would be said that the men in the navy were picked men, but that fact might be offset with the further fact that they were of the age when phthisis was most likely to develop, seafaring men, usually occupying bad quarters for sleeping. The ratio of deaths from phthisis in the navy to deaths from all other causes was 6·3 per cent., while in Colorado, Florida, and Mississippi the ratio was 8+per cent. In Texas, Arkansas, and Arizona it was about 6 per cent., or nearly the same as on the ocean. According to English statistics, the mortality from phthisis was ten times less on the ocean than on land; if allowance was made for the seaman's age, from fifteen to forty-five years, it was sixteen times less. The rate of mortality from consumption among all classes who lived on the water in this country, including canal and river men, and their wives and children, was less in comparison with the general mortality than that of several of the New England States. Consumptives on land, subjected to like conditions, would certainly die much faster. More than thirty years ago he had kept records of the mortality occurring on vessels on the west coast of Africa, and found that the number of deaths from phthisis was greater at a given locality where the atmosphere was dry than at points where there was greater moisture, which went to show that moisture alone was not the cause of greater mortality among the phthisical. An atmosphere containing clean moisture was by no means necessarily promotive of consumption. If one wished to experience the full benefit of the Adirondack region he should go into it, and not remain on its outskirts. There one would get the benefit of free drainage, atmospheric agitation, electrical change, and a bountiful supply of ozone, equal to that developed by the action of the waves on the seashore. He had examined the maps prepared by Dr. Denison very carefully, and, while he held in admiration the industry displayed by the author, he certainly was far from being willing to accept his suggestion to make excessive dryness, to say nothing about altitude, the test of climate for consumptives.

Dr. REED was glad to hear the vigorous protest of Dr. Bell against the suggestions offered by the author. When Dr. Denison read his paper last spring he (Dr. Reed) had entered his protest against accepting his conclusions. He thought it was so generally admitted by the profession that ocean air, either on shipboard or at the sea-coast, was beneficial to consumptives that there ought to be no longer any question about it. It had been a known fact among physicians since the time of Hippocrates, and had never been questioned until recent years, when it had become the fashion to talk about dryness as the only standard. He had been glad to hear the explanation by the president of the importance of dryness of the soil. Against the idea that dryness was the only important factor he could place his observations at Atlantic City, where patients suffering from phthisis, particularly in the first stage, and often in the second stage, did very well. These maps, which showed elaborate work and were unquestionably valuable, also contained conclusions which required restrictions. They could not be accepted as proof positive. Regarding the statistics of the English navy referred to by Dr. Bell, in a paper which Dr. Reed read last spring he had given some of the records of both the navy and army of England, which were to the point. Of course the men in both the army and navy were equally picked men

and it was a striking fact that, while there was quite a fair proportion of deaths from phthisis in the army, in the navy, if he remembered correctly, the mortality from the same cause was not more than a third as great. The only way to account for this greater mortality from phthisis in the army was that the men were on land, while those in the navy were most of the time at sea.

The President remarked that it was evident the association was not willing to indorse Dr. Denison's position, and it was hardly necessary to take a vote upon it.

Dr. Tyndale, the reader of Dr. Denison's paper, stated that the author's contention was that the principal features of climate related to dryness, elevation, and equability of temperature. Statistics had thus far shown that, of these three, dryness was the most important, and equability next, elevation being third, and not separable from dryness.

[Note by the Author.—The author wishes to add a word or two in reply to those who took part in the discussion. First, with reference to the president's criticisms. A considerable number of physicians, whose opinions are most trustworthy, have critically examined the charts and have not found them at all confusing, when applying the given explanations to the colors, lines, arrows, etc., illustrating separate data.

The comparatively favorable Adirondack region was not differentiated on the seasonal charts, because the Signal Service had no station there. Undoubtedly the freedom from soil-moisture and the "quick drainage" would so have made its impress upon the humidities of the atmosphere as to have brought out this region into one of the light-red colors of moderate dryness. The qualities which the president mentions as favorable—porosity of soil, "quick drainage," and, in fact, all the soil conditions which produce a pure atmosphere—extend over large areas in the United States. These regions, because of their atmospheric dryness, are thrown into the deep-red shades on the seasonal charts; on the other hand, the dark-blue regions, showing atmospheric moisture, indicate a general preponderance of opposite soil characteristics. Therefore, for large regions, the character of the soil, in a great measure, determines the atmospheric humidities. Conversely, the humidity colors, to a certain extent, represent soil conditions.

The president's statement that the author's position is not indorsed is unfair, since the whole discussion, with the above-mentioned exception, was irrelevant to the subject of the paper read—namely, *the even divisions of climate*. The question is, Are the divisions of climate fair, and the extremes on the charts worked out with justice to the sections of our country which are put in opposition to each other?

The discussion seems to have been wholly confined to the therapeutics of climate, which the author did not intend to introduce in this paper. As to his previous writings he has nothing to retract; nor has he ever said that dryness was the "*only*" important factor in climate. If, however, he were to mention the principal features of climate, for the arrest of phthisis, in the order of their importance, he would give them as *dryness*, *coolness*, *sunshine*, and *elevation*, not mentioning *equability* at all, for he would expect to find a due amount of *variability* with these favorable attributes.

Provided he is present at some future meeting of the association, he would be pleased to discuss the subject introduced by these gentlemen. Perhaps the following title will best comprehend the questions in dispute, *i. e.*, *The comparative importance of different climatic attributes in the arrest of phthisis.*

However, there were two statements made which should not go uncorrected, notwithstanding they are foreign to the discussion of the author's proposed divisions of climate. With reference to Dr. Bell's argument, mortality statistics from consumption are inadmissible as settling the salubriousness or injuriousness of given climates, because of the migration of pulmonary invalids in search of health. For instance, if statistics of mortality from pulmonary tuberculosis alone are taken, probably not over five per cent. of such deaths in Colorado have been from disease which originated in the State. The author has written many certificates of death from phthisis—probably a hundred and fifty, and perhaps more—during his twelve years' residence in Denver, but he does not remember to have written one for an uncomplicated case which originated in Colorado. A brother physician suggests that one might as well assert that all the cases of syphilis at Hot Springs, Arkansas, originated there.

That sea-air is healthful, and the mortality among seamen is small, is not at all to be wondered at, since the analyses of the air by Miquel, at the Observatoire de Montsouris, near Paris, have shown that the air out at sea is next in freedom from bacteria to that of elevated regions. Therefore if, in addition to this purity of sea-air, the consumptive mortality among seamen —some six per cent.—is about equal to that in Texas and Arizona, where many invalids go, then the better—the dryer and more elevated—portions of those States must indeed furnish a very pure atmosphere, and one which is especially suited to the consumptive's needs.

If Dr. Reed's statement, that the maps "contained conclusions which required restrictions," does not indicate a determination to shun the inevitable logic of facts, it is at least very vague. There are no "conclusions" on the maps except the arithmetic of climatic data—the condensed and graphical illustration of the work accomplished by the Signal Service Bureau. Why should not the conclusions of facts be allowed to have full sway in the judgments of medical men who are able to appreciate their bearing? In fine, with reference to a many-sided question like the one introduced, is it not through the largest collection of facts and climatic data that the physician can have any reasonable grounds from which to draw conclusions? And is it not a mistake to try to determine those conclusions from an experience which is limited to sections which are within a hundred or so miles of New York city?]

HYDRONAPHTHOL;
A NEW ANTISEPTIC.

By GEORGE R. FOWLER, M. D.,
SURGEON TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

(*Continued from page 459.*)

The following is a *résumé* of the antiseptic methods employed in this hospital with hydronaphthol:

Preparation of Sponges.—Medium-sized sponges of good quality are selected and thoroughly beaten so as to break up and loosen all calcareous particles. These are thoroughly washed until all gritty matter is separated. They are then placed in a solution of permanganate of potassium of the strength of thirty-six grains to the pint, and there allowed to remain for a few minutes, or until they are of a brown color. They are then washed in clean water and placed in a bleaching solution made as follows:

Sodium hyposulphite.....	10 ounces;
Water	68 "

Dissolve, and add muriatic acid, 5 ounces.

This solution should be made the day before required for use, so that the sulphur may separate from the solution. It should be decanted off. The sponges should be immersed in this solution for a few moments only. They

should then be washed in clean water, and, in order to make certain that no sulphurous acid remains, it is well to immerse them a few moments in a solution of bicarbonate of sodium, 100 grains to the pint. They are then sterilized by being immersed in a 1-to-1,000 solution of corrosive sublimate for two hours. From this they are transferred to a 1-to-1,000 warm solution of hydronaphthol and kept hermetically sealed in a screw-cap fruit-jar or museum-jar. If it is desired to keep them in a dry state, glycerin should be added to the last-named solution, in the proportion of half an ounce to the pint, in order to prevent the sponges from becoming harsh and brittle. For hospital use, a separate jar is kept for each day's supply of sponges, and, as soon as they are no longer required, they are washed thoroughly, again sterilized as before, and placed in the hydronaphthol solution in the jar in which they belong, which is numbered for purposes of identification, and not put to use again until at least a week has elapsed. This insures the most perfect immunity against infection from every source, and enables one to employ the same sponges again and again without incurring the slightest risk.

Irrigation.—During operations and dressings an almost constant stream of hydronaphthol solution, 1-3,000, in water previously sterilized by boiling, is kept running over the parts. The jar containing the irrigating solution is kept partly filled with the saturated solution, and, at the time of operating or otherwise employing the irrigating solution, warm water is added in the jar in sufficient quantity to reduce it to a weaker solution.* In cases of chronic joint disease or cases of hydrops articuli, if no purulent accumulation be present, the hydronaphthol is used to wash out the joint. If, upon tapping the joint, purulent or floeculent fluid flows through the cannula, a solution of corrosive sublimate is first used to thoroughly sterilize the interior, and this is, in its turn, well washed out with the hydronaphthol solution. By this means corrosive-sublimate poisoning is guarded against; a portion of the hydronaphthol solution may be left in the joint cavity. In all cases of a septic character sterilization had best be accomplished by the aid of the mercuric-bichloride solution, the latter being always washed away subsequently with the hydronaphthol solution.

Bath for Instruments.—The instruments are placed in shallow pans, porcelain-lined, and covered with a saturated solution of the compound. A towel, wrung out of the same, is spread out in a convenient place, upon which the operator drops the instruments when not in use, and from which an assistant transfers them to the bath until again needed. Towels for the purpose of isolating the field of operation are wrung out of a 1–1,000 mercuric-bichloride solution.

Preparation of Catgut.—The catgut should be wound upon hard-rubber, glass, or porcelain spools. It is then sterilized in a one-per-cent. solution of mercuric bichloride, being immersed for twelve hours. It is then transferred to an alcoholic solution of hydronaphthol, one tenth of one per cent., for permanent preservation. The latter hardens the gut sufficiently, and preserves it against all further change.

Silk and horse-hair may be treated in the same manner, excepting that they may be boiled in the corrosive-sublimate solution for a half hour and then immersed for twelve hours. They should be preserved in the alcoholic hydronaphthol solution, as in the case of the catgut.

Drains may be immersed in the corrosive-sublimate solution also, in the same manner as the catgut, and then placed, for permanent preservation, in a saturated watery solution of hydronaphthol, to which glycerin, in the proportion of half an ounce to the pint, has been added.

Wood-flour and Sawdust.—Sterilization of wood-flour and sawdust is accomplished by thoroughly triturating the same in a mortar with an alcoholic solution of corrosive sublimate, and in the same solution the hydronaphthol is dissolved, which latter gives to the dressing its permanent antiseptic character. The following is a good working formula for this purpose:

Hyd. biehlor., Hydronaphthol,	āā	3 ss.;
Glycerin		℥ j;
Spts. rectif.		Oj.

This should be triturated with 3 pounds of wood-flour, or finely-sifted sawdust, and, after drying, placed in bottles with large mouths until required for use. Bags are prepared, of different sizes, of coarse cheese-cloth previously rendered hygroscopic by boiling in a strong alkaline solution, and then washed and dried. The material known as mosquito-bar or netting, if used, need not be rendered hygroscopic, as its meshes are so coarse as to readily permit of the passage of the wound secretions through and into the wood-flour. These are dipped into the same solution prepared for the wood-flour or sawdust, before filling. They are prepared and filled upon the day of operation, and kept in a tin can, or wrapped in some impervious material until needed.

Absorbent Cotton.—This is used for backing up and placing around the edges of the cushion or pad dressings, when these are placed upon uneven surfaces. It is hydronaphtholated in an alcoholic or benzol solution, so that the former represents twenty per cent. of the cotton by weight.

Absorbent Gauze.—This is hygroscopic cheese-cloth; what is known among dry-goods dealers as archery bunting makes a very good dressing after being rendered hygroscopic. It is hydronaphtholated in the same manner as the cotton, and, after drying, kept in tin cans until needed for use. It is used principally for making bandages. Should it be designed for use in immediate contact with the wound, it is prepared in the same solution used for the wood-flour, in order to insure its thorough sterilization by means of the mercuric bichloride.

*Paper-wool.**—This is manilla tissue-paper, cut into strips one sixteenth of an inch wide and saturated with the same solution used for the wood-flour. It is passed through the rolls of a clothes-wringer, dried and carded, or pulled apart by hand. It is used as a cushion-dressing, or may be applied in a mass directly to the wound.

* Solutions of from 1-3,000 to 1-5,000 are sufficiently strong for all purposes. The saturated solution, although generally well borne, has seemed at times to over-stimulate the tissues and lead to increased secretion, a very undesirable feature in any antiseptic agent.

* See article in "N. Y. Med. Jour.," October 10, 1885.

Hydronaphthol Soap.—Powdered soap, triturated with about four per cent. of hydronaphthol, is found to be most convenient for use. The compound may be incorporated in cakes of ordinary toilet soap with advantage. It is useful in scrubbing the parts preparatory to operation, the surgeon's hands, etc.

Hand Scrubbing-Brushes.—These are kept in a saturated solution of the hydronaphthol. Two sets are always at hand, one for cases in which some suspicion of sepsis is entertained and suppuration exists, and the other for aseptic cases and the surgeon's hands.

Mention has been previously made of a hydronapthol-ated magnesia for use as an absorbent along the line of sutures. I think that this is uncalled for in the majority of instances, and in antiseptic surgery whatever is uncalled for had best be omitted. Wherever such an application is needed, this will be found a safe and efficient substitute for iodoform.

In addition to these, hydronaphthol incorporated in simple ointment, in the proportion of half a drachm to the ounce, is found to be an excellent application when a stimulating ointment is indicated. Old leg ulcers and the like are found to behave very kindly and heal rapidly under its use.

Dr. F. W. Rockwell, chief of our department of genito-urinary diseases, informs me that he has had some excellent experiences with hydronaphthol in cases of purulent cystitis, washing out the bladder once or more daily with a saturated solution. In a case of irritable bladder of long duration, in a female, I recently dilated the urethra so as to admit my index-finger, for exploratory purposes. An acute cystitis followed, which yielded readily to a daily irrigation with a warm solution of this compound.

A case of intractable eczema capitis recently yielded rapidly to the application of the hydronaphthol ointment. I believe the naphthols have been employed in the Vienna skin clinics for some time past with marked benefit.

To summarize the results of my experience thus far with this compound I would state that: 1. It is an efficient and safe antiseptic and anti-putrefactive agent. 2. This is accomplished in very dilute solutions; consequently it compares favorably in point of expense with carbolic acid, and it is especially as a substitute for the latter that its use is urged, not only on the score of cheapness, but of safety. 3. Its saturated solution is only of the strength of 1 to 1,100, and consequently no mistakes can occur in its use. In this strength of solution it is at least five times above its antiseptic limit, and yet is non-poisonous, non-corrosive, and, generally speaking, non-irritant.

COCAINE AS AN ANÆSTHETIC IN FRACTURES AND DISLOCATIONS.

By JOHN R. CONWAY, Jr., M. D.,

INSTRUCTOR IN CLINICAL SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ASSISTANT CURATOR TO BELLEVUE HOSPITAL.

Dr. M. Josiah Roberts's experiments on the use of the hydrochlorate of cocaine in bone surgery first suggested to my mind that it could be applied with equal success to a fractured bone, and the soft tissues surrounding it, to render them perfectly anæsthetic, and thus allow of careful and painless examination, and, if necessary, the manipulation required for the reduction of a deformity of the fragments.

It is obvious that, if this could be done successfully and safely, it would be a valuable addition to the resources of the surgeon for accurately diagnosticating the line of fracture, reducing displaced fragments, and, finally, painlessly setting the broken bone.

The manipulation of a fracture necessarily causes great suffering, and, if there should be a displacement of the fragments, the agony of reduction without an anæsthetic is always very severe.

Of course, ether or chloroform can be given, but the inconvenience of so doing and the disagreeable after-effects, not to mention those during the administration, are generally sufficient to prevent the use of either, the pain being considered the lesser of two evils.

I believed, also, that the ligaments and tissues surrounding a joint could be anæsthetized by the use of the cocaine, so as to allow of a painless reduction of a dislocation.

I resolved, accordingly, to test the effects of cocaine in the first set of cases that presented themselves.

Below I have recorded three cases of Colles's fracture in which the solution was used with marked success, and one case of dislocation backward of both bones of the forearm at the elbow-joint, where it acted with equal satisfaction.

Case I.—A. T., aged thirty-seven, a painter by occupation, was admitted into Gouverneur Hospital, October 26, 1885. While he was painting the cornice of a house the scaffolding on which he was standing gave way, precipitating him to the ground, a distance of over thirty feet. He struck upon his right buttock and the palmar surface of his right hand. Examination showed that he had received a fracture of the right radius, about three fourths of an inch from the lower extremity of the bone, the lower fragment having been displaced backward upon the upper, and being firmly held in that position. He had, also, severe contusions about the right hip and buttock, but no other serious injury.

All attempts at an examination of the injured forearm caused him so much pain that I concluded to use deep injections, at the point of fracture, of the four-per-cent. solution of cocaine, and ascertain whether it would sufficiently anæsthetize the bone and the tissues surrounding it to allow of a thorough examination and of reduction of the deformity without causing him pain. I loaded a hypodermic syringe with twenty minims of the four-per-cent. solution, and inserted the needle perpendicularly into the posterior surface of the forearm, directly over the seat of fracture, and pushed it down into the tissues until the point could be felt on the bone and between the fragments; there the solution was slowly injected until three minims were discharged. Withdrawing the needle slightly, so that its point would rest in the soft tissues just over the fractured bone, I injected two minims more. On the outer side of the radius I adopted the same procedure, endeavoring in the deepest injection to push the point of the needle far enough anteriorly to leave two minims in the tissues in front of the fracture, as well as the three minims between the fragments in this situation. In withdrawing the needle I injected two minims into the soft parts covering the fracture externally. The third injection was made between the ulna and radius—three minims between the fragments at this point, and two into the parts covering them. Altogether, seven-

teen minims were used. I think it is very important that the cocaine should not only reach the fractured surfaces of the bone, but should also be injected into the tissues immediately surrounding the fracture, for, although the bone may be thoroughly anæsthetized, the manipulation necessary for examination and reduction will sufficiently disturb the injured soft parts to cause pain, unless they also are rendered insensitive. After completing the last injection, I immediately applied a rubber bandage to the arm above the elbow, to check the circulation, and thus render the anæsthesia as lasting as might be desired, a method first suggested and practiced by Dr. J. Leonard Corning, of this city. (See "N. Y. Med. Jour.," Sept. 19, 1885, p. 317.) In five minutes from the time the needle was first introduced there was complete anæsthesia all about the seat of fracture. Firm pressure, and even blows on the forearm over the injured bone, caused no uncomfortable sensations.

Flexion, extension, and lateral motion of the wrist joint were made without any complaint from the patient, and, when questioned, he assured me that he felt no pain.

This was all in marked contrast to his sensations and complaints before the cocaine was used. Then he could not bear the least pressure over the fracture, and any motion of the joint caused him great agony. After I had satisfied myself, by a thorough examination, that there was no doubt as to the fact that absolute anæsthesia was produced, I proceeded to reduce the deformity by extreme extension of the wrist joint, together with traction. This was successfully accomplished at the first trial, although considerable force had to be used. The patient bore the reduction very calmly, never making the least sign that would show he was being hurt, and, when asked if it pained him, he answered "No!"

I now had the fragments in proper position, and could readily move them upon each other, producing distinct crepitus. Rubbing the broken surfaces of the bone together was unattended by the slightest symptom of pain.

The rubber bandage was allowed to remain on at least half an hour, and at the end of that time the anæsthesia was as profound as in the first ten minutes after the cocaine was introduced.

After the removal of the bandage, sensation returned to the parts at the seat of fracture in about fifteen minutes, but the pain was not excessive, nor sufficient to give rise to any complaints.

Case II.—J. O'B., eight years old, a school-boy, was admitted into Gouverneur Hospital, October 29, 1885. He had been knocked down while playing in the school-yard and fallen forward, striking upon both hands and knees. Examination revealed a Colles's fracture of the right radius with dislocation of the lower fragment backward. The injured wrist was very sensitive, and could not be touched without causing a good deal of pain.

In this case I used fifteen minims of the four-per-cent. cocaine solution in divided injections in the same manner as in the preceding case. Instead of checking the circulation with an elastic bandage, digital compression of the brachial was employed. As before, complete anæsthesia was produced in a little over five minutes, and the patient bore the manipulation necessary for examination and reduction of the displaced fragment without complaint.

After the circulation was allowed to go on again the fractured bone and soft parts regained their sensibility in about ten minutes.

Case III.—J. S., aged twenty-seven, a varnisher, was admitted into Gouverneur Hospital on October 30th suffering from a backward dislocation of both bones of the left forearm at the elbow joint. Any motion of the dislocated joint caused pain. The parts were also very sensitive to pressure. Twenty-five minims of the four-per-cent. cocaine solution were used in five separate injections of five minims each. The punctures were made around the joint at equal distances apart. The needle was first pushed as deep as the ligaments, and three minims were discharged; then it was withdrawn slightly, and two minims were injected into the soft parts covering the ligaments. Having finished the injections, I encircled the arm with a rubber bandage, and so checked the circulation. Allowing ten minutes to elapse, I examined the joint at the expiration of that time, and found that the ligaments and deeper tissues were perfectly anæsthetized. Motions of the displaced joint were made in all directions without causing pain. Reduction was effected by means of forced flexion, together with traction of the forearm and counter-extension of the arm, with scarcely any sensation to the patient. As the bones were slipping into place he muttered an exclamation, but said that he "did not feel it much." I then removed the bandage from the arm, having allowed it to remain on about half an hour, and all that time the anæsthesia had continued profound. Sensation remained absent for ten minutes and then returned.

Case IV.—M. D., aged forty, a 'longshoreman, fell and received a Colles's fracture of the left radius on November 2d. There was no displacement of the lower fragment, and the symptoms of fracture were somewhat obscure. There was a good deal of tenderness about the wrist. I injected ten minims of the four-per-cent. solution in two injections between the fragments on either side of the bone. The circulation was not checked, as the examination could be made rapidly, and prolonged anæsthesia was not necessary. After five minutes had elapsed I found the bone anæsthetized, and could rub the fragments together and get crepitus without causing any suffering.

In this case I had not injected the solution into the soft tissues over the fracture, and therefore found that they were not without sensation, for, although scraping the bones together caused no pain, extreme flexion or extension of the wrist was attended by uncomfortable sensations. The anæsthesia did not last more than ten minutes.

In conclusion, I would like to state that, if the injections are made carefully in the manner described in Case I, and the circulation is checked, after five or ten minutes have elapsed anæsthesia will certainly be produced in a fracture, and will continue until the blood is allowed to resume its course through the vessels. In dislocations a greater quantity of the cocaine has to be used, and the punctures must surround the joint as nearly as possible, and the solution be injected not only into the ligaments, but also into the soft tissues immediately around the joint.

In none of the cases that I have experimented in have bad effects followed the introduction of the cocaine. On the contrary, I think the inflammation was checked and was not so severe as it would have been had the cocaine not been used.

14 Lexington Avenue, *November 16, 1885.*

A PLEA FOR CREMATION.*

By WILLIAM M. McLAURY, M. D.

In the course of human events, laws, customs, ceremonies, and even habits of thought change. There is a law of progression that manifests itself through individuals as well

* Read before the Society of Medical Jurisprudence and State Medicine, October 8, 1885.

as nations. There are more indications of peaceful progress of our race toward higher modes of life now than ever before in the history of mankind. One change that is inevitable, and becoming more and more necessary for health and comfort in our nation, is in the disposal of the dead. By our habits of thought, by our laws, by our religious ceremonies, we are silently and solemnly taught that to reverently deposit the remains in a grave dug beneath the ground is the only way of showing proper respect to our departed friends. And with many, no doubt, the religious sentiment taught of the physical resurrection of the body would continue to be a great objection to their giving consent to substitute cremation for inhumation. But safety for the living with change in religious sentiments must in time overcome all such scruples.

The Oriental nations that have practiced cremation for cycles of time are more philosophic and hygienic than we who selfishly plume ourselves on our highly enlightened Christian civilization.

Greece in her palmiest days cremated her dead. The ancients held to four elements in Nature—air, water, earth, and fire, the latter being the most powerful, as it is capable of changing, purifying, and destroying each of the others.

In our own country, with its vast extent of soil and climate, there is a great difference in the danger to the living from the inhumation of the dead. In country places, where the population is not dense and the location of the cemetery is hygienically chosen, the danger to the living may be said to be very slight. But, as our country becomes older and more populous, the danger becomes increased in a geometrical proportion. It will be conceded by all that cemeteries in the vicinity of cities are a source of increasing danger to those cities. Take the city of New Orleans, for instance, where the graves can not be dug so as to bury beneath the surface; hence the coffins are placed on the surface and mounds are built over them. In process of time some of these become leveled and broken; consequently the escaping gases from putrefying corpses poison the air for miles around, threatening seriously friends and employees who attempt to repair the damage. Not only is the air poisoned by cemeteries, but water in the vicinity. Wells are sunk in close proximity to decaying bodies, and I have often myself perceived the cadaveric odor in drinking water of wells so situated.

Dr. Gray, of Orange, N. J., whom I met at Ocean Beach this summer, told me of a well in his town so near the cemetery that the men, while digging a grave, being driven from their work by a sudden and violent thunder-storm, as they returned to their work found the grave nearly filled with muddy rain-water, and, as they repaired to the nearest well for drinking-water, found the well-water also muddy, and, on extending their observations, found a subterranean communication between the grave they were digging and the well, which they proved by filling the grave with water and finding a corresponding rise of water in the well.

I have often seen graves dug where the water had to be bailed out repeatedly while the grave was being dug, and bundles of straw or hay thrown in just before the coffin was lowered, to prevent the mourners hearing the coffin splash into the water.

By cremation we avoid another horrifying thing in regard to burial—it is the vermin infesting grave-yards. It is a fact well known by all grave-diggers that rats are abundant in grave-yards and burrow from grave to grave, gnaw the coffins, and feed on the dead bodies so tenderly and reverently placed there. All these things, so distressing to sympathetic friends and mourners, would be avoided by the simple, cleanly, reverent deposition of the dear friend's or relative's body in the fragrant retort gleaming with rosy light.

We can not overestimate the sanitary agency of heat; it is the only thing that will utterly destroy the cryptogamic spore and annihilate the mycelium. Freezing renders microbia dormant and inactive, but they easily thaw into life again, and become as active and propagative as ever.

If we will only rationally compare the difference between burial and cremation, we may see how much there is *every way* in favor of the latter. The slow putrefaction, the offensive stench, the miasmatic effluvia, the poisonous gases of contagious diseases and plagues, the burdensome expense of funerals—all, all are avoided by the simple, economical, healthful reduction of the human remains to ashes by the chemical agency of heat amid the fragrant odor of sweet spices.

From the legal side of the house we may hear the objection against cremation that, in cases of crime (felonious poisoning, for instance), the evidence of the crime is immediately and for ever swept into oblivion. I would say, in reply to this objection, that the changes going on in society through this and other improvements in life will so elevate the standard of public morals and so modify the selfishness of individuals that heinous crimes of cruelty against the person will be of very rare occurrence. Radical improvements in the customs, habits, and ceremonies of a people or nation never go singly. A change of this kind would rid the people of an immense amount of superstition. It would be economic as well as hygienic. It would economize labor as well as material, and thus save thousands of dollars to poor people, who annually bury an immense amount of money which is greatly needed for food and raiment for the survivors. This they waste and bury, thinking that thereby they honor the dead. When we lighten the burdens of the poor we lessen crime. Criminals are made so by the hardening systems under which they live.

We are still living in the midst of error. We look back and commiserate the people of the "dark ages." A few generations hence people will look back to our time and wonder why we did not reform abuses and correct our errors.

It is pertinent for this society, in its domain of State medicine, to suggest feasible methods as to the erection and establishment of crematories in all towns and cities where the public health makes it necessary for their establishment, and have the entire business as a department of State.

But we have first to agitate and educate the public mind up to such a condition that it will think and act upon the subject. This may be done by issuing tracts and circulars and

through the daily press, and directing earnest attention to it through national and State offices and officers. The various boards of health would be powerful aids in helping to mold public opinion.

To the members of this society, or the public who wish to further investigate this subject, I would recommend a very able paper read by my friend, Dr. P. C. Coal, before the Northwestern Medical and Surgical Society, and also to a more lengthy paper by Dr. E. J. Bermingham, published by him in 1881.

I would also call attention to an excellent paper by John O. Marble, M. D., of Worcester, Mass., published in the "Medical Communications of the Massachusetts Medical Society," vol. xiii, No. iv, 1885.

Book Notices.

The Science and Art of Midwifery. By WILLIAM THOMSON LUSK, A. M., M. D., Professor of Obstetrics and the Diseases of Women and Children in the Bellevue Hospital Medical College, etc. New Edition, Revised and Enlarged. With Numerous Illustrations. New York: D. Appleton & Co., 1885. Pp. xviii–763. [Price, cloth, $5; sheep, $6.]

IN the short space of time that has elapsed since the first edition of Professor Lusk's treatise appeared, its reception by the profession has been such as amply to justify the commendation with which we greeted it. It has become a recognized text book in nearly every American medical college and in many of the British schools; it is read and quoted wherever the English language is spoken; and translations of it are announced in French, Italian, and Spanish. It is safe to say that it is generally regarded as the leading treatise on obstetrics, and that it is likely to maintain that position for many years to come.

The new edition contains nearly a hundred more pages than the first one, and twenty more illustrations. The number of the chapters and the phraseology of their titles remain the same, so that the changes have been interstitial, *i. e.*, of just the kind that a careful and painstaking revision should bring about. This means that the original work was so comprehensive and so well arranged that additions were needed only as to matters of detail. No higher praise than this can be given to any treatise on a practical branch of medicine. The book is now beyond criticism, for it has been accepted by the unerring judgment of the great body of physicians. We congratulate Dr. Lusk upon this reward for the immense labor he has bestowed upon it.

A Treatise on the Science and Practice of Midwifery. By W. S. PLAYFAIR, M. D., F. R. C. P., Physician-Accoucheur to H. I. and R. H. the Duchess of Edinburgh; Professor of Obstetric Medicine in King's College, etc. Fourth American, from the Fifth English, Edition. With Notes and Additions by ROBERT P. HARRIS, M. D. With Three Plates and Two Hundred and One Illustrations. Philadelphia: Lea Brothers & Co., 1885. Pp. xxv–34 to 663, inclusive.

THE appearance of a new American edition of this popular work will awaken considerable interest among students of obstetrics, inasmuch as the author's preface promises much. However, after a careful perusal of the book, it is impossible to avoid the conclusion that many questionable paragraphs have been retained, and that the most modern portions of the book are the work of the American editor.

It is unnecessary to discuss at length the character and scope of a work which is so familiar; it will be more profitable to note such improvements as have been made (or their absence). There are comparatively few changes in the chapter on anatomy; the brief paragraph upon the perinæum (page 53) preserves its original form in spite of the criticisms of former reviewers. As regards the woodcuts, it is sufficient to say that the bad ones are as bad as ever, although the worn-out state of the plates might have justified a few fresh drawings. Figures 34 and 35 are not pleasing to look upon. Chapter V, on the Differential Diagnosis of Pregnancy, deserves enlargement. In the light of modern improvements in the methods of diagnosis, the reader will be disappointed in it. The operative treatment of abnormal pregnancy belongs properly to that portion of the book which treats of obstetric operations. Chapter XVI, on Rupture of the Uterus, concludes with a long paragraph by Dr. Harris, who urges the performance of laparotomy "in all cases of rupture where it is evident that blood and liquor amnii have escaped into the abdominal cavity." His note on Porro's operation (page 526) is of value because of the exhaustive statistics it gives. The introduction of a separate chapter on Laparo-Elytrotomy (Chapter VII, page 529) is a graceful tribute to American surgery. Considering the amount which has been written of late on the conduct of natural labor, especially on the management of the perinæum, expression of the placenta, and the after-treatment of the puerperal woman, Chapter III (page 280) does not exhibit those evidences of revision which we should expect. The chapter on Puerperal Septicæmia likewise contains no reference to the recent American discussion on that subject.

In considering Professor Playfair's work as a whole, it can not be said that he has given that care to its revision which we should expect in view of the fact that it has not a few formidable rivals in the field. The reception which greeted Lusk's book ought to have been a convincing proof that the profession is not slow to recognize true scholarship. Every new edition of a well-known work must be abreast of the times, or it will surely be replaced by more advanced books. With all due kindliness toward the writer, we must acknowledge that Playfair's "Midwifery" is still just a little bit antiquated.

BOOKS AND PAMPHLETS RECEIVED.

Practical Surgery; including Surgical Dressings, Bandaging, Fractures, Dislocations, Ligature of Arteries, Amputations, and Excisions of Bones and Joints. By J. Ewing Mears, M. D., Lecturer on Practical Surgery and Demonstrator of Surgery in Jefferson Medical College, etc. With Four Hundred and Ninety Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1885. Pp. 794. [Price, cloth, $3.75; sheep, $4.75.]

The Principles and Practice of Surgery. By John Ashhurst, Jr., M. D., Professor of Clinical Surgery in the University of Pennsylvania, etc. Fourth Edition, Enlarged and Thoroughly Revised. With Five Hundred and Ninety-seven Illustrations. Philadelphia: Lea Brothers & Co., 1885. Pp. xxviii–33 to 1118, inclusive.

Clinical Therapeutics. Lectures in Practical Medicine, delivered in the Hospital St. Antoine, Paris, France, by Professor Dujardin-Beaumetz, Physician to the Cochin Hospital, etc. The Treatment of Nervous Diseases, of General Diseases, and of Fevers. Translated by E. P. Hurd, M. D., etc., Newburyport, Mass. Detroit: George S. Davis, 1885. Pp. xvii–491.

A Reference Handbook of the Medical Sciences, embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Authors. Illustrated by Chromo-litho-

graphs and fine Wood Engravings. Edited by Albert H. Buck, M. D., New York City. Volume I. New York: William Wood & Co., 1885. Pp. vi–808.

The Principles and Practice of Medicine. By the late Charles Hilton Fagge, M. D., F. R. C. P., Physician to, and Lecturer on Pathology at, Guy's Hospital, etc. Including a Section on Cutaneous Diseases, by P. H. Pye-Smith, M. D., F. R. C. S., Lecturer on Medicine at Guy's Hospital; Chapters on Cardiac Diseases, by Samuel Wilkes, M. D., F. R. S., Physician to Guy's Hospital, etc.; and Complete Indexes, by Robert Edmund Carrington, M. D., Assistant Physician to Guy's Hospital, London. Volume I. Philadelphia: P. Blakiston, Son, & Co., 1886. Pp. 1040.

An Atlas of Clinical Microscopy, by Alexander Peyer, M. D. Translated and Edited by Alfred C. Girard, M. D., Assistant Surgeon, United States Army. First American, from the Manuscript of the Second German Edition, with Additions. Ninety Plates, with One Hundred and Five Illustrations, Chromo-lithographs. New York: D. Appleton & Co., 1885. Pp. xiv–194. [Price, $6.]

Inorganic Chemistry, by Edward Frankland, Ph. D., D. C. L. LL. D., F. R. S., Professor of Chemistry in the Normal School of Science, London, and Francis R. Japp, M. A., Ph. D., F. I. C., Assistant Professor of Chemistry in the Normal School of Science, London. With 51 Illustrations and a Plate. Philadelphia: Lea Brothers & Co., 1885. Pp. xix–33 to 693, inclusive.

Des névroses réflexes d'origine nasale. Par le Dr. A. Cartaz, etc. [Reprinted from "France médicale."]

Observations upon the Mutual Relations of the Medical Profession and the State. Address by Donald Maclean, M. D., President Michigan State Medical Society, delivered before the Society at Port Huron, June 10, 1885.

Avena Sativa in the Treatment of Opium Addiction. A Therapeutical Fraud, a Delusion, and a Snare. By J. B. Mattison, M. D., Brooklyn. [Reprinted from the "Medical Bulletin."]

Mechanical Dilatation of the Uterus. By Charles Meigs Wilson, Philadelphia. [Pamphlet.]

Correspondence.

LETTER FROM WASHINGTON.

The New Library and Museum Building.—Medical Officers on Duty Abroad must Pay their own Expenses.—The International Medical Congress.—Georgetown University.—The New Nomenclature of Diseases.—The Inspection on the Canadian Border.

Washington, *November 23, 1885.*

The new Medical Library and Museum building is growing apace, and the brick wall is to be seen on three sides. It is thought that, should the winter be not very severe, the work will be pushed without ceasing, so that the building may be ready for the roof by early spring.

Much sympathy is felt with Surgeon Billings on account of the recent ruling of the accounting officers of the Treasury Department whereby he is obliged to pay from his own pocket the expenses of his trip to Europe in attendance upon the meeting of the International Medical Congress and in the collection of books and pictures for the library. This trip was evidently, as is reported, mainly for the latter purpose, and its results are already manifest in valuable additions to the library. Furthermore, the journey was made under the orders of the Secretary of War. It is understood that a similar ruling will be made on the traveling-expense accounts of Medical Director Brown, of the navy, who attended the same congress. The immediate effect of this ruling will be that these details will not be sought after as in the past. It looks to an unprejudiced observer as if medical men scarcely had an equal chance with other classes of our fellow-countrymen. An army officer of good looks, a graduate of the military free academy, and of undoubted pedigree, can with little trouble get an order taking him to witness the spring manœuvres at Saint Cyr, the mobilization of the *Landwehr*, or perhaps the actual hostilities between contending forces, but who ever heard of an order detailing a doctor to witness the establishment and hygienic management of the hospitals abroad, or of the quarantine service? It is only recently that we have gained enough in that direction to allow of the sending of an expert to study the cholera epidemic, and one to participate in the sanitary conference.

The President was waited upon by a committee from the Local Committee of Arrangements of the International Medical Congress to-day. Dr. J. M. Toner, Dr. C. H. A. Kleinschmidt, Dr. J. B. Hamilton, and Dr. A. Y. P. Garnett, the chairman, were present.

The Medical Department of the Georgetown University have in contemplation the erection of a new building for college purposes. The plans contemplate the erection of a structure worthy of this old institution and the National Capital. Dr. J. W. H. Lovejoy, the Dean of the College, has been confined to his room for the last two weeks on account of sickness.

Captain Henry F. Azpel, of the Medical Department of the Army, has been in the Hospital for the Insane for several months, and has recovered so far that a jury has decided him to be of sound mind and refused to appoint a guardian for his estate. It is probable that he will soon be released and returned to duty.

Major Ben. Perley Poore's index to the publications of the Government is now being issued by the Public Printer, and it is well for collectors to remember that any book published by the Government may be purchased at cost price, with ten per cent. added, if the purchase is made while the work is passing through the press.

The Surgeon-General of the Marine-Hospital Service is daily receiving applications for copies of the revised Nomenclature of Diseases, but it is authoritatively stated that the original work will be issued to the service, and no American edition will be published by that department, as was done in the case of the first edition. Gentlemen desiring the revised Nomenclature will therefore be obliged to depend upon their booksellers.

Owing to the outbreak of small-pox in Prince Edward's Island, and its extension to the Province of New Brunswick, the Marine-Hospital Service has begun an inspection service on the eastern frontier. The health authorities of Ontario have made representations to the Surgeon-General to the effect that they are inspecting persons and baggage from Montreal with great care, that they are taking every necessary precaution, and that they therefore wish the inspections on the border discontinued as against the Province of Ontario. No statement is made in regard to the fumigation of Quebec baggage by the provincial authorities; hence there is some doubt expressed as to the wisdom of the proposed relaxation of the present precautions.

NEW YORK, SATURDAY, DECEMBER 5, 1885.

ESMARCH'S BANDAGE IN LOCAL ANÆSTHETIZATION BY FREEZING.

IN the "Lyon médical" for November 15, 1885, there is a somewhat lengthy article on this subject by Dr. Chandelux. It appears that some time since M. Horand, having observed that local anæsthesia by refrigeration was unusually difficult of attainment in very vascular tissues, conceived the idea of passing a ligature around the part, thus effectually arresting the circulation in the region to be refrigerated before the application of the ether spray. By resorting to this expedient, insensibility was much more rapidly induced than when the blood was allowed to circulate in the part. All this might have been readily predicted beforehand, since it is evident that the blood constantly circulating in the capillaries carries continually to the tissues a quantity of heat, which is effectively opposed to the refrigerating influence of the spray. Hence the inevitable evanescence of the insensibility induced by refrigeration *even if we shut off the blood-flow to the part*, for, unless we operate in an ice-vault or a refrigerator, we shall always have the calorific influence of the external atmosphere to contend against. We are therefore not surprised to learn that the duration of the anæsthesia induced by refrigeration, even when the spray is used *after* arrest of the circulation by the application of the ligature, is *only three minutes*.

Dr. Chandelux's improvement upon the suggestions of M. Horand consists in this, that, before applying the ligature, he exsanguinates the part by means of an ordinary Esmarch bandage. This is the whole story of the achievement. It is true that the time necessary to produce insensibility of the part is sensibly abbreviated over and above that required by M. Horand, who has recommended the ligature alone; but the duration of the anæsthesia after it has been established is *only three minutes;* hence the question, What is to be gained by an anæsthesia which is far briefer in duration than that obtainable by the use of a few drops of a solution of cocaine, even when the latter is employed without Dr. Corning's precautions?

But, putting aside the merits and demerits of Dr. Chandelux's proposals, it must be remembered that among many surgeons of eminence to-day the question is, not how shall we freeze, but shall we freeze at all? The devitalizing consequences of freezing to the tissues are often indeed disastrous. As Mr. Thomas Bryant remarks ("The Practice of Surgery," Philadelphia, 1879), freezing mixtures, when too long applied, "may produce frost-bite or chilblain"; and Dr. John Ashhurst, speaking of the same subject, observes ("The Principles and Practice of Surgery," Philadelphia, 1878): "The process of freezing is itself very painful in some instances, especially when mucous membrane is involved, as in the case of hæmorrhoids, and the use of the ether spray is not entirely free from danger; thus in a case of excision of the tunica vaginalis for hydrocele, which occurred in this city, the use of the spray was followed by extensive sloughing of the scrotum, which well-nigh cost the patient his life." There is probably not a single surgeon of extensive experience but can bear witness to such major calamities as the direct result of anæsthesia by freezing—this at least is true when operations at all considerable have been attempted.

In the face of such facts it is with pleasure that we recur to the method recently proposed by Dr. J. Leonard Corning, of this city (see the number of this journal for September 19th), which, after repeated trials by various surgeons, seems to leave nothing to be desired in point either of profundity or of duration of the anæsthesia, the latter quality being practically unrestricted.

The chemical method of inducing local anæsthesia seems, then, to embody the only principles which are really practicable; and, since by Dr. Corning's method solutions of one and even one half per cent. of cocaine hydrochlorate may be employed, there is practically no danger of constitutional symptoms of the graver sort, if even ordinary caution is employed. The possibility of preventing too rapid an escape of the incarcerated anæsthetic into the general circulation, by gradually loosening the constricting ligature or tourniquet, would seem to afford additional security of a physiological and substantial sort. The only surgical exploits performed under Dr. Chandelux's method of freezing have been the removal of some ingrowing toe-nails and the incision of a felon—very pretty little operations, certainly, but this is not the extirpation of large tumors, nor yet excision of the hip joint. Dr. Corning's method seems to fulfill the scientific ideal; the closer the analysis to which its various details are subjected, the more do the latter appeal to physiological intuition and common sense.

SURGEON BILLINGS'S EXPENSE ACCOUNT.

WE are not willing to admit that the decision of the accounting officers of the Treasury Department, whereby a man who has served the country so notably as Surgeon Billings, of the army, is placed in the unpleasant position of having to pay out of his private resources the expenses incurred by him while acting under orders from the Secretary of War, will be confirmed or treated as final. The sympathy felt with Surgeon Billings in Washington, as mentioned by our Washington correspondent, is by no means confined to the Capital, and we do not believe that it is limited to the army or to the medical profession. It is not too much to say that, if the ruling is carried into effect, the nation will be felt to have assumed a humiliating attitude before the world. Without asserting now that there may not have been technical considerations to warrant or excuse the decision, we must insist that the fundamental facts in the case are such as should make the Government utterly refuse to allow it to be enforced.

Among the acts for which the American Government is

most respected abroad are the production of the Index-Catalogue of the Library of the Surgeon-General's Office and the intelligent and liberal management by which the library itself and the museum have been brought to their present state. It was doubtless a gratification to Dr. Billings to attend the Copenhagen meeting of the International Medical Congress, but the fact must not be lost sight of that his presence at the Congress, advantageous as it undoubtedly was to our prestige as a country in which the demands of medical science are not wholly ignored, was far more demonstrably in the interest of the great public undertakings of which he has charge in greater or lesser degree. By his being enabled to visit the chief sources of accretions to the library and to the museum he was unquestionably put in a position to direct even more intelligently than before the purchase of books and apparatus for those institutions, and consequently to save the Government many an item of unnecessary expense that could not otherwise have been well avoided. At all events, he went, as we understand it, not merely with the permission but by the direction of the Government, and we can not see that his journey can be looked upon in any other light than as in the line of duty.

MINOR PARAGRAPHS.

THE CITY HEALTH DEPARTMENT.

It is mortifying to reflect that one of the commissioners, the president of the board, has been arraigned on a charge which involves his integrity in certain financial transactions, but it is gratifying to know that these transactions had nothing to do with his career as a Health Commissioner, and also that the accused is not one of the medical members of the board. A Senate committee, however, is investigating the methods which have crept into the doings of the Board of Health since he became its president, and the result may be somewhat opposed to the general impression that a layman is needed to manage the medical members of such a body. The facts thus far brought out have been well known in the profession, but the general public has probably had not the slightest inkling of their significance or even of their existence.

FREE TRADE IN DOVER'S POWDER.

It is notorious that any householder, or for that matter any servant girl, in New York can at any time obtain a Dover's powder of almost any apothecary in town by simply asking for it and paying for it. A prescription is not at all necessary, and no questions are asked. A transaction of this sort lately resulted in the death of an infant, as it is supposed, and the apothecary has been tried and acquitted on the charge of having given Dover's powder instead of another remedy that had been prescribed by a physician. His defense is said to have been that the child's mother asked him for Dover's powder, and that he made no mistake. In view of the loose custom prevailing, it is not easy to see how any other conclusion of the case could have been reached, but the occurrence ought to call the attention of apothecaries and that of the officers of the law anew to the need of enforcing the same restrictions on the sale of Dover's powder that are in force in the case of certain poisons that are more dangerous, it is true, but not so much more dangerous as to justify their classification apart.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 1, 1885:

DISEASES.	Week ending Nov. 24.		Week ending Dec. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	2	2	3	0
Typhoid fever	33	9	22	8
Scarlet fever	39	9	33	5
Cerebro-spinal meningitis	3	3	3	3
Measles	17	5	8	1
Diphtheria	72	23	75	29
Small-pox	7	2	3	2
Yellow Fever	0	0	1	1

A Pretended Vaccination.—The Springfield, Mass., "Republican" is credited with the story of a Vermont woman who, having occasion to travel on a Montreal train, determined to outwit the sanitary inspector by making him think that she had recently been vaccinated. Accordingly, she sewed a button to the inner side of her sleeve, at the usual site of vaccination, and, when the inspector asked her to show her arm, answered that it was not necessary, for he could "feel the scab." The device is said to have succeeded.

Hospital Saturday and Sunday.—The Hospital Saturday and Sunday Association has taken measures which ought to secure an increase of this year's fund over that contributed last year. The plan relates chiefly to the auxiliary trade-organizations, but there seems reason to hope that the churches and the synagogues will improve on their past contributions.

A Confectioner's Clinic may be said to have been held in the Court of General Sessions last Monday, the occasion being that of the trial of a firm of confectioners on a charge, brought forward by a sanitary official, of having used tainted cocoanuts in the production of some of their goods. A member of the firm ate a large quantity of the sweets, and so did some of the jurymen, all with evident relish. The result was that the complaint was dismissed. The sanitary officer has since stated that the sweets eaten in this demonstrative manner were not of the lot on which he had founded his complaint.

Personal Items.—Dr. Charles E. Sajous, of Philadelphia, was among the passengers by the steamship Noordland, which arrived at New York from Liverpool November 27th.

The University of Santiago de Chile.—According to the "Deutsche Medizinal-Zeitung," Dr. R. Ewald, of Strassburg, has been called to Santiago de Chile as professor of physiology.

The German Hospital.—Dr. H. J. Garrigues has been appointed gynæcologist to the hospital, in place of Dr. E. Noeggerath, resigned.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 22 to November 28, 1885:*

Winne, C. K., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon at Benicia Barracks and Attending Surgeon at Benicia Arsenal, California. S. O. 109, Department of California, November 20, 1885.

Reed, Walter, Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension, to take effect about December 1, 1885. S. O. 115, Department of the Platte, November 18, 1885.

Taylor, A. W., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect December 5, 1885. S. O. 116, Department of the Platte, November 20, 1885.

CHAPIN, A. R., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Robinson, Nebraska. S. O. 115, Department of the Platte, November 18, 1885.

SIMONS, JAMES, Lieutenant-Colonel, U. S. A. (retired), died November 11, 1885, at Baltimore, Md.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending November 28, 1885.*

DRENNAN, M. C., Surgeon. Ordered to Training-ship New Hampshire.

AULICK, H., Surgeon. Detached from Training-ship New Hampshire, and to wait orders.

FITTS, H. H., Assistant Surgeon. Ordered to appear before examining board preliminary to promotion.

RUSH, C. W., Past Assistant Surgeon. Granted sick leave for three months, from November 20, 1885.

MARMION, R. A., Surgeon. Detached from Marine Barracks, Washington, D. C., December 7, and to wait orders.

MOORE, A. M., Surgeon. Ordered to Marine Barracks, Washington, D. C., December 7, 1885.

Society Meetings for the Coming Week:

MONDAY, *December 7th:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians (annual); Morrisauia Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conu., City Medical Association; Chicago Medical Society.

TUESDAY, *December 8th:* New York Medical Union (private); New York Surgical Society; Medical Societies of the Counties of Chemung (Elmira) and Rensselaer, N. Y.; Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private); Medical Society of Morris County, N. J. (semi-annual); American Public Health Association (Washington, D. C.—first day).

WEDNESDAY, *December 9th:* New York Pathological Society; American Microscopical Society of the City of New York; Medico-Legal Society; Medical Societies of the Counties of Cayuga (semi-annual), Cortlandt (semi-annual), and Montgomery, N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society (conversational); American Public Health Association (second day).

THURSDAY, *December 10th:* Harlem Medical Association of the City of New York; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; New York Laryngological Society (annual); South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia; American Public Health Association (third day).

FRIDAY, *December 11th:* Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.; American Public Health Association (fourth day).

SATURDAY, *December 12th:* Obstetrical Society of Boston (private).

Proceedings of Societies.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Meeting of November 16, 1885.

The President, Dr. CHARLES A. LEALE, in the Chair.

Photographing Wet Preparations.—Dr. J. W. S. GOULEY described a method of taking photographs of wet preparations which had been new to him five years before, when he first practiced it. It consisted in attaching the specimen to a blackboard and immersing it in clear water in a glass jar. Transferring the specimen from alcohol, the usual preservative fluid, to one of a different density caused the finer as well as the coarser filaments to float and stand out prominently from the mass of the specimen and to present a distinct appearance in the photograph. A number of beautiful photographs, taken according to this method and illustrative chiefly of the diseased bladder, were exhibited, and contrasted with others of the same specimens taken while they remained in alcohol. The latter were indistinct and unsatisfactory, while the former represeuted the irregularities of the lining membrane in minutest detail.

The Elements of Prognosis in Bright's Disease.—Dr. AUSTIN FLINT read a paper with this title. In the popular miud the name Bright's disease at the present time had a prophetic import not unlike that of a verdict of conviction after a trial for life. It was regarded as a hopelessly fatal malady. This prevailing impression reflected the views of the medical profession, that a fatal termination would invariably take place sooner or later. This view accorded with our pathological knowledge and clinical experience. But the scope of prognosis was not limited to recovery from the disease. A disease might involve more or less irremediable damage to important organs, but, after having progressed to a certain extent, the damage might not become greater, and the remaining healthy portion of the organs might be sufficient for all purposes of life and a perfect state of health. Again, a disease might be progressive, but so slow as not to be opposed to long life and general good health. But in chronic disease the danger to health might depend upon associated affections, or chronic disease might be tolerated, provided the conditions were favorable; otherwise it would prove fatal. Was the disease acute or chronic? Assuming the existence of acute Bright's disease, experience taught that, exclusive of the important concomitant affections, it did not end fatally as a rule, and did not result in any permanent renal lesion. In other words, the acute was not followed by the chronic disease; but exceptionally it ended fatally or in the chronic form. In some cases the acute disease was not marked; it continued for some time, and ended in recovery. Here he would substitute for the word acute, subacute. In some cases the question would arise, whether the disease was subacute or chronic, and the diagnosis could only be definitely settled in favor of the subacute form by the disappearance of every evidence of renal disease after some weeks, and the recovery of health.

The author then considered some of the elements of prognosis in cases of chronic Bright's disease. What were some of the conditions requisite for latency? 1. The kidneys must not be damaged beyond a certain degree. 2. The important organs of the body, other than the kidneys, must be capable of performing their respective functions satisfactorily. 3. The laws of health relating to alimentation, exercise, etc., must be observed. Suppose these conditions to be fulfilled, and a lesion of the kidneys to exist which diminished their functional ability one half, and the disease was not progressive; life and health would be compatible with the existence of chronic Bright's disease for an indefinite period. In order that chronic Bright's disease should be well tolerated, the treatment should relate to accessory conditions required for bringing about toleration, those conditions relating to other organs of the body and to general hygiene. The kidneys in this condition were incapable of meeting an additional demand on their functions. Should the patient fail to observe the accessory conditions mentioned, the inefficiency of the kidneys would become manifest in headache, misty vision, nausea in the morning, impairment of the

appetite, and general debility. Examine the urine in such a case, and evidence would be found of chronic Bright's disease which had probably existed for years, the progress of the renal affection at length rendering the organs incapable of performing their functions properly, which caused attention to be directed to the state of the kidneys. It was important, in determining whether the kidneys eliminated excrementitious matters sufficiently not to endanger the health, to make a thorough examination of the urine, not alone with regard to the presence of albumin and casts, but also as to the amount of urine eliminated daily, its specific gravity, and the proportion of the salts. The quantity of the urine might be increased while the specific gravity was so low as to involve great danger from uræmic toxæmia. Suppose the examination of the urine in a case of chronic Bright's disease showed renal adequacy; how should that fact influence the treatment? In this way, that diuretics, sudorifics, and hydragogue cathartics would not be indicated; indeed, inasmuch as their influence was debilitating and opposed to the accessory conditions for health just mentioned, they were contra-indicated. Was the degree of renal adequacy, as determined by an examination of the urine, reliable in judging of the absence of danger from toxæmia? This question was to be answered in the negative. In some cases of Bright's disease the quantity of the urine was decreased for a long period without serious consequences. The explanation lay in the fact that the excrementitious matter was eliminated vicariously, or its effects upon the system were counteracted by other agents. On the other hand, slight inadequacy, without vicarious elimination and counteracting agents, sometimes led to serious consequences. The prognosis after coma was always grave, yet we met with cases repeatedly in which life was preserved for a long time. Of acute pulmonary œdema the same might be said as of uræmic coma. In his experience the most serious consequence of Bright's disease was dyspnœa, or renal asthma, apparently due to toxic effects upon the respiratory center. He had never known such a case to end in recovery, but he had known life to be prolonged for several years after dyspnœa from pulmonary œdema occurring in the course of chronic Bright's disease.

Recapitulating, Dr. Flint said that subacute diffuse nephritis, having the same seat and characters as acute Bright's disease, exclusive of acuteness, occurred not only after scarlet fever and other fevers, but irrespective of these; and when it occurred as a primary affection, or in connection with other diseases, it was liable to be overlooked, or, if recognized, to be mistaken for the chronic form. Further, acute or subacute diffuse nephritis not infrequently occurred as an intercurrent affection in the course of chronic Bright's disease, and rendered the prognosis temporarily more serious. The disappearance of symptoms and the presence of health did not necessarily indicate that the chronic disease was not still in existence. Again, a susceptibility to the causes of inflammation of the uriniferous tubules, irrespective of the existence of chronic Bright's disease, was to be recognized as an individual peculiarity.

Dr. G. L. Peabody said that from his limited experience he could corroborate all the conclusions drawn by Dr. Flint. He would emphasize the statement that Bright's disease of a serious character might remain latent for a great many years in persons whose circumstances were such that no particular strain was put upon the vital organs. He very frequently found at post-mortem examinations evidence of advanced Bright's disease in people in whom it had not been suspected during life. It seemed to him also very important to calculate the extent to which the kidneys were performing their function of elimination, as Dr. Flint had suggested. It was natural, on finding albumin and casts in the urine, to make in our minds a grave prognosis, and perhaps find the prognosis not borne out by the facts. But, with people who were obliged to expose themselves to hardships, Bright's disease might terminate fatally at almost any time.

Dr. E. G. Janeway had heard only a part of the paper, but said he would speak with regard to prognosis very much in the same strain in which Dr. Peabody had spoken. He had seen cases of chronic Bright's disease which seemed to warrant a prognosis of the gloomiest kind, yet, the patients' circumstances permitting of travel in the South during the winter, and of living according to prescribed rules, life had been prolonged many years. Again, we saw not infrequently an intermittent element in chronic Bright's disease—cases in which, for a considerable period, albumin and casts might be absent, and again present. The co-existence of rigid arteries, especially if there was marked hypertrophy of the left ventricle, rendered the prognosis more serious.

Dr. E. M. Moore, by invitation, discussed the paper, and asked how long any of the gentlemen had known acute or subacute Bright's disease, following scarlet fever, etc., to exist without becoming chronic.

Dr. Flint replied that the duration varied from two or three weeks to four or five weeks, perhaps sometimes longer. When the disease had existed a year it must be chronic.

Dr. Moore mentioned a case in which the symptoms of Bright's disease, as manifested in the urine, had existed at least a year, yet the patient recovered. He thought the period during which the symptoms of Bright's disease could exist and complete recovery take place was greater than was generally supposed.

Forceps Delivery; Death from Typhoid Fever; Malarial Pigmentation in Several Organs.—Dr. E. G. Janeway presented some specimens removed from the body of a woman who had been delivered three weeks before her death with forceps under unfavorable circumstances, giving rise to the suspicion of puerperal septicæmia; the diagnosis of typhoid fever, however, was made in Bellevue Hospital, one symptom in particular pointing to this disease—namely, diarrhœa. The patient had been cured of an attack of malarial fever two months before her confinement. The autopsy showed marked malarial pigmentation of the liver and spleen; also the lesions of typhoid fever in the intestines. The case was interesting from a diagnostic point of view; there had been reasons for believing that it might be one either of puerperal fever, of typhoid fever, or of malarial fever. Dr. Janeway had seen a number of cases in which typhoid fever had developed during the puerperal state, and probably an error in diagnosis occurred not infrequently.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of November 11, 1885.

The President, Dr. John A. Wyeth, in the Chair.

An Enormous Double Hernia.—The President presented a part of the genito-urinary tract, and about ten feet of the large and small intestine contained in the sacs of a double hernia which measured about forty inches in its greatest diameter. The patient, fifty-three years of age, was admitted into Mount Sinai Hospital on the 28th of October, 1885. The hernia on the left side had been present for seven years. It had not been reduced for three years, but had caused no discomfort. The one on the right side was larger, and had existed only three or four weeks. The specimen was interesting chiefly on account of its great size, it being the largest hernia which the President had ever seen. During the past year he had seen a case in which the tumor was not quite so large, having a similar history.

Chronic Myo-Carditis and Chronic Interstitial Nephritis.—Dr. JOHN C. PETERS presented microscopical specimens illustrating these lesions in the case of a bachelor, sixty seven years of age, of regular habits, delicate in appearance, but who had not been sick for thirty years or more.

Dr. W. M. CARPENTER had examined the heart and kidneys, and said that there were also slight changes in the uriniferous tubules, but not such as would lead him to expect to find marked indications of the same in the urine. The epithelial lining of the tubules seemed to be sufficiently sound for them to discharge their function almost perfectly.

Double Hydrocele in an Infant.—Dr. VAN SANTVOORD presented a specimen illustrating double hydrocele in an infant which had died at the age of two months.

Lupus of the Larynx.—Dr. VAN SANTVOORD also presented the larynx of a boy, aged fourteen years, who died of lupus commencing in the nose. The disease had destroyed the nose, the upper lip, the alveolar processes between the canine teeth, and the hard and soft palate. The nasal septum had fallen out, and the sphenoid bone was bare and rough. There was thickening of the mucous membrane of the larynx, and that which lined the ventricles and their immediate neighborhood was studded with nipple-like processes, the summits of which were of the size of the head of a pin. The immediate cause of the death was a feature of interest in the case. The boy had lived with comparative comfort until about five days before death, when he was seized with severe headache, which passed on to delirium, coma, and death. The base of the brain was found coated with a dense layer of lymph, distributed about as was usually seen in tubercular meningitis, but no tubercles were observed. The body of the sphenoid was necrotic, and had given rise to the meningitis. The lungs were œdematous; the liver, spleen, and kidneys were markedly waxy. The case also seemed of to be interest in connection with the alleged identity of lupus and tuberculosis. The local disease was very extensive, yet tubercles had not been found in any portion of the body. The specimen had not yet been examined for bacilli.

Dr. M. PUTNAM JACOBI did not think the clinical history of the case could be accepted as weighing against the alleged identity of lupus and tuberculosis, for it was evident, from the statements of Hüter and König, that a localized tuberculosis in the skin and bones seldom became general. Supposing the lupus in this case to have been a tuberculous process, we need not be surprised that general tuberculosis had not developed.

Dr. T. M. PRUDDEN remarked that tubercle bacilli were found in a large number of cases of lupus, and that, if a tuberculous inflammation could be defined as one in which the tubercle bacillus was present, then the identity of the two diseases was established.

Cancer of the Stomach and Tuberculosis of the Retro-Peritoneal Glands.—Dr. LOUIS WALDSTEIN presented microscopical specimens from a young man who some years before had suffered from chronic pneumonia in the left apex, from which he had recovered. Two years ago he suddenly showed symptoms, as was then believed, of remittent fever, which continued for two years, antipyretics having no curative influence upon the fever. The physician who examined him two years ago detected a tumor in the epigastrium, which he regarded as cancer, although there had been no particular gastric symptoms. The patient was seen by a number of physicians in consultation, and one detected an enlargement in the abdomen, apparently a continuation of that in the stomach. At the autopsy a caseous focus was found in the apex of the left lung, and the bronchial glands were enlarged and contained many caseous spots. In the stomach there was a diffuse scirrhus, which showed no tendency to ulceration. The retro-peritoneal glands were very much enlarged, and had undergone cheesy degeneration. There were no cancerous foci elsewhere in the body.

Dr. PETERS remarked that it had formerly beenc onsidered that the presence of one of these diseases precluded the other.

The PRESIDENT thought that it was now considered that where both were present the one retarded the growth of the other.

Necrotic Cystitis.—Dr. PRUDDEN presented the bladder of a woman who for a month had been paralyzed upon the right side; had complained of pain only in the lower part of the back; and at one time had had difficulty in passing water, but lately had urinated without trouble. There was albumin in the urine; no examination was made for casts. The autopsy revealed a tumor occupying the left half of the pons, basilar meningitis, and pachymeningitis purulenta of the petrous bone and the posterior portion of the sphenoid. The lesion in the bladder was of interest in connection with a specimen presented at a recent meeting by Dr. Boldt, being a cast of the bladder from exfoliative cystitis; here the condition of the viscus was shown just before the stage of exfoliation. The bladder was distended with rather turbid urine. The mucous membrane was moderately red. At the neck of the bladder there was a patch of tissue, about three inches in diameter, denuded of epithelium, which had the appearance of œdematous connective tissue, rather sharply outlined by an irregular band of yellow, the seat of purulent infiltration and softening. The round area was fibrous, and contained some elastic fibers; the white and yellow patches contained urinary salts, and some bodies which would probably be found to be mucin.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of November 23, 1885.

The President, Dr. DANIEL LEWIS, in the Chair.

AN adjourned annual meeting was first held, and after that the stated meeting.

An Address by the President was read, in which he said that medicine had a commercial side, and he called attention to some of the tendencies of recent times to degrade the profession to a trade level. It had once been considered unprofessional to employ or to recommend medicinal compounds the ingredients of which were not known, but now it was nothing unusual to see physicians' names attached to laudations of medical compounds of almost every description. No professional man could afford to place himself in the position of recommending a remedy when it could be suspected that he did so for a monetary consideration. Our materia medica was extensive enough, and our therapeutics sufficiently perfected to enable any intelligent practitioner to prepare his own prescriptions, and to avoid any recognition of the patent-medicine men who infested every community.

Numerous plans for securing patients were now tolerated which had once been unknown—unknown even to the younger men of the profession. We received advertisements of Swedish movement cures and of medicated baths, and read in the papers of infirmaries and sanitary homes conducted by the eminent Professor ——, with a large corps of assistants. There could be but one cause for this unseemly strife for medical business, and that was overcrowding of the ranks. So long as New York city had a physician for every four hundred and fifty inhabitants, the young physician would have to invent a new splint, run for the office of coroner, or start a new life insurance company with the hope of obtaining some patients. In order to attain to any standing in the eyes of the community at the present time it was necessary that the young physician be con-

nected with a dispensary or some other medical institution. Overcrowding of the profession was responsible even for the abuse of medical charity. At a former meeting he had expressed his conviction that a State medical examination would be the most potent means for overcoming these difficulties. Within the past few days a distinguished superintendent of a lunatic asylum, the president of the New York State Medical Association, had publicly declared that the interests of all concerned were best subserved by the present methods of admission to practice. Our leading colleges now furnished better aids than formerly, it was true, but they were too commercial in their organization to be highly scientific, and one or another of them would graduate anybody who applied for a degree; if a student failed to get his diploma at one school, he always succeeded at another. If the proposed State examination should be nothing more than our best schools required, it would at least keep out those who were totally unqualified to obtain diplomas, but which they had nevertheless obtained from schools without the State and had had indorsed here by the payment of twenty dollars. It was Dr. Lewis's belief that if the society would lend its full influence toward securing a State examination, as had been proposed, it would succeed, and the regeneration of the profession in New York would thereby be assured.

The President then thanked the society for the honor it had conferred upon him by electing him to office a second time.

Committees for the Ensuing Year.—The President appointed the following committees: *Hygiene*, Dr. E. H. Janes, chairman; Dr. Alexander Hadden, Dr. Cyrus Edson, Dr. John C. Peters, and Dr. W. L. Hardy; *Ethics*, Dr. George A. Peters, chairman; Dr. M. Blumenthal, Dr. C. C. Lee, and Dr. W. T. Alexander; *Prize Essays*, Dr. F. R. Sturgis, chairman; Dr. F. P. Foster and Dr. W. R. Birdsall; *Auditing Committee*, Dr. P. A. Morrow, chairman, and Dr. G. Bacon.

Cleft Palate.—Dr. Norman W. Kingsley presented a boy with cleft palate, who pronounced as well as he could certain words, that the audience might have an opportunity to contrast his speech at that time with what it would be after an operation, when Dr. Kingsley hoped to present the patient again.

The Mechanical and Operative Treatment of Knock-knee and Bow-leg Deformities; with a Description of New Forms of Apparatus and New Operations.—Dr. M. Josiah Roberts read a paper with this title, which he illustrated with drawings, photographs, and instruments. He said that, however good the results might be in some cases of bow-legs and knock-knee when they were left to nature, better results could always be obtained in a much shorter time by intelligent treatment. Whenever patients came to the surgeon with deformities of this character, although only slight in degree, they should receive treatment. He referred to a paper read before the Medical Society of the State of New York, in which he had described the outlines of the lower extremities when of natural form, and in which, by the use of instruments of precision which he named, any variation from this normal standard could be determined. Minor degrees of deformity, which nevertheless were disagreeable to the patient, might be overlooked by the surgeon unless the patient removed his clothing and went through the motions of walking, running, etc. To do away with the necessity of nudity, he had had a tightly fitting knit garment made.

The author then proceeded to the description of in-knee, and said the deformity might be associated with spinal caries, lateral curvature, hip disease, and various forms of developmental deficiencies. One form of in-knee was associated with exaggerated extension of the joint, another with flexion, the planes of inclination of the right and left thigh and leg being different in these two instances. Cases of the latter deformity were usually of paralytic origin. In still another class of cases knock-knee existed with inversion of the feet; they were usually of idiopathic origin. In another class there was in-knee flexion with outer rotation of the leg on the thigh, due usually to struma, or rheumatic arthritis, or infantile paralysis. Knock-knee might be associated with anterior curvature of the tibia, or of the tibia and fibula. Knock-knee and club-foot might be associated, and, when that was the case, they were commonly of paralytic origin. In another class there was knock-knee with outward bowing of the shaft of the femur—a rare combination. A common deformity was that of bow-legs and anterior lateral curvature or bowing of the lower third of the tibia. Again, cases were met with of rhachitic arrest of development associated with knock-knee or bow-legs, or with both of these deformities. Occasionally one leg was seen affected with in-knee and the other was bowed. Simple anterior curvature of the tibia was likely to be of traumatic origin. Dr. Roberts then presented instruments by which the degree of these various deformities could be determined with exactitude. Among the new ones was one for simultaneously observing and recording any possible combination of angles at a given articulation. By another, the surgeon was enabled to measure the base of a wedge of bone which it was necessary to remove in order to correct any given deformity. It also enabled him to determine the exact size of the wedge-shaped pieces to be removed from the tibia and femur when both bones were deformed. The author then described his form of elastic splint for overcoming knock-knee, which was a modification of that previously employed by Dr. Davis. He also described a simple but efficient osteoclast. The use of this, however, he did not consider justifiable, and he had employed it only to a limited extent. As to chisels, he had obtained and used those acknowledged to be of the best form and quality, and he could say unqualifiedly that it was impossible to remove a clean wedge-shaped piece of bone with any of them, either on the living or on the dead subject. The result was always unworkmanlike. A serious objection to the cross-cut saw was that, under the circumstances in which it was used, its to-and-fro motions were necessarily limited, and the teeth could not clear themselves of *débris;* hence, the operation was very tedious and unsatisfactory. He then exhibited the working of the electro-osteotome, which had been perfected in so far that it was now entirely under the control of one hand, and admitted of the use of either the circular or cross-cut saw, or the gouge.

The Willard Parker Hospital.—A letter from Dr. E. H. Janes, of the Board of Health, again called the attention of physicians to this hospital, which had been established for the reception of patients with certain contagious diseases.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of November 3, 1885.

The President, Dr. W. R. Birdsall, in the Chair;
Dr. G. W. Jacoby, Secretary.

Ophthalmoplegia Externa.—Dr. Leonard Weber read a history of the case of Peter N., aged fifty-two, father of a number of apparently healthy children. He had worked in an iron foundry for the last thirty-two years. His mother died of pulmonary hæmorrhage at fifty-four years of age; his father died, at fifty-three, of typhoid fever. A brother and sister were still living, in good health. He had never had syphilis. Fourteen years ago he was under treatment for hæmoptysis, accompanied by fever and other signs of acute lung trouble. But he recovered in the course of a year or so, and had been able to continue his work since. Nevertheless, the signs of old pulmonary trouble were well marked in the interscapular space,

particularly on the right side. In the course of years the patient sustained various injuries about the head, but no fracture of the skull. At no time did his condition give any evidence of renal or cardiac disease. Since February 1, 1885, he had experienced considerable and lasting pain at the back of the head on the right side. In getting out of bed on the morning of February 23d, of the present year, he felt somewhat dizzy, and noticed a pain in the right temporal, extending to the occipital region. He also found that he could not use his eyes as on the night before. He continued to work, however, and on March 9, 1885, consulted Dr. Mittendorf, who reported that the use of the patient's right eye had been lost early in childhood. The left eye had given him no trouble until recently. On March 9th both eyes were found to have turned considerably toward the nose. Neither could be moved outward. The pupils were slightly contracted, and the accommodation was good. Hypermetropia existed, rendering the use of a strong glass for the left eye necessary to make reading possible. Vision with the right eye, which had a corneal macula, was very poor. The acuity of vision of the left eye—not fairly tested, the patient presenting himself at night—was about $\frac{2}{3}\frac{0}{0}$. There was marked hyperæmia of the left disc. The interior of the eyes was normal. The paralysis extended to the third nerve, but was not complete. The patient would move his eyes downward considerably at times, but he seemed to have lost control over the movements of the muscles, and, if directed to look in a certain direction, he could not do it. On March 17th he first noticed some numbness and a cold feeling from the fingers up to the middle of the arm on the right side. While this sensation was unpleasant, it in no way interfered with his work of using a heavy hammer. But about April 15th the arm became weak. At the same time co-ordinate muscular action became impaired. He was unable to direct blows with precision, often striking an inch to either side of the object. He soon had to quit work.

He consulted Dr. Weber on May 14th. At that time the eyeballs were almost immovably fixed. Nevertheless, there was complete paralysis of the external recti only. The levatores palpebrarum were not affected; neither were the muscles of the iris. The right hand was colder than the left. The sense of touch was diminished, as was also actual muscular power. There was visible trembling, with gradual dropping of the wrist when the extremity was extended horizontally, showing weakness of the extensors. Slight exaggeration of patella tendon reflex existed on the right side. There was some dysarthria, but no dysphagia, and no symptom indicating disturbance of cerebral nerves other than the fifth pair. The gait was unsteady, resembling that described by Nothnagel in connection with certain cerebellar affections. Dr. Weber was inclined to locate the lesion producing the foregoing symptoms in the pons. As to its nature, it was probably a neoplasm of syphilitic or tubercular origin.

The patient was ordered iodide of potassium in doses at first of ten grains three times a day, which were increased by five grains every week. In this way the dose was carried up to forty grains three times a day. Noticeable improvement began in June, and by September 2d the patient's speech had become almost normal, the power of his right arm was much increased, there was no more headache, and the eyes had largely recovered their mobility.

On October 30th it was observed that the eyes could be moved freely, although some paresis of the external recti still remained. The patient was then taking forty-five grains of the iodide three times a day. Some spitting of blood occurring, the remedy was discontinued for two weeks, and resumed with an initial dose of twenty grains.

The anatomical lesion was believed to be situated in the left half of the pons, near the tegumentum, involving the lemniscus, and extending beyond the rhaphe some little distance into the right half of it.

Dr. W. H. Mittendorf said the author of the paper was to be congratulated on the result of the treatment in this interesting case. As had been stated in the paper, when the patient visited him there was this paralysis of the external recti, and he thought there was also a slight defect of the facial nerve, so that he had been inclined to place the lesion in the upper part of the fourth ventricle; but, as motor-oculi paralysis developed, he came to the conclusion that there was a more extensive lesion than he had at first supposed. An interesting feature in the case was the fact that, while there was ophthalmoplegia externa, there was at no time, while the patient was under his care, any affection of the intrinsic muscles, and this fact, according to recent investigations, would point to a lesion below the aqueduct of Sylvius. Cases of ophthalmoplegia externa without other symptoms were very few. He had now under his care a young man with ophthalmoplegia affecting both eyes, in whom there had been no change for two years. The lesion, he supposed, was to be placed in the region of the corpora quadrigemina. At one time he had thought there were real ataxic symptoms, but had been unable to make out a clear case of locomotor ataxia.

Dr. T. R. Pooley had never seen a case of complete paralysis of the ocular muscles with so satisfactory a result.

Dr. Weber remarked, in reply to a question by Dr. Spitzka, that there had been no wasting of the muscles, although the general nutrition had not been at all times equally good.

The President had reported two cases to the American Neurological Society which in some respects resembled this one, but in some others there were important differences. He had reported them as cases of ophthalmoplegia externa, according to Hutchison's nomenclature, and they were, strictly speaking, cases of this sort. The ciliary muscle and the iris were not involved at any time, while the external muscles of both eyes were involved to a greater or less degree. No other nerve-tract in the body could be found defective. The two patients had remained about in the same condition, with slight improvement, for two years. It seemed to him, however, that the cases which Hutchison had reported under the name of ophthalmoplegia externa did not all belong to that class, for in only two or three had the external muscles of the eye alone been affected. Most of his cases were of a complex character. It seemed to him that the pathology must vary greatly. The lesion would probably be found to vary not only in location, but also in character. His cases, he thought, were due to a slow degenerative form of disease, similar to that of progressive muscular atrophy. Certainly some of Hutchison's cases were of a multiple character, and probably in many others the lesions were multiple.

Dr. E. C. Spitzka said that he had been much pleased to find a doubtful point in the past history of this case cleared up by Dr. Pooley's discovery of a residual paresis of the other rectus externus. It added, however, to the difficulties of localization, though not incompatible with Dr. Weber's diagnosis. With regard to Dr. Pooley's suggestion, that the loss of skilled motion on the right side was due to the eye trouble, that possibility had already been taken into account, and disposed of for the following reasons: First, the motor disturbance was not present when the eye trouble was at its height, nor was it present when the latter began. He believed ophthalmologists would agree that locomotor trouble was apt to be proportionate to the intensity of the eye complaint, and, if anything, to be regulated provided the eye trouble remained stationary or improved. In this instance, however, we had eye trouble at its maximum without arm trouble, and arm trouble developing as the eye

trouble improved, and manifested when the eyes were closed. Besides, it must be borne in mind that, as the patient had not had the use of his right eye from childhood, he would not be so likely to be disturbed in his movements as patients with binocular vision would be.

He believed the oculo-motor disturbance could be best accounted for by a regional extension of the lesion in that part of the tegumentum which lay between the trochlearis and abducens nuclei, and where certain co-ordinating tracts ran. He should have an opportunity, perhaps, of demonstrating specimens of a case in which but one special conjugate movement of the eyes was interfered with and there was a neoplasm in and near the abducens level, chiefly unilateral.

Dr. Weber asked Dr. Mittendorf whether there had not for a time been symptoms of hemianopsia.

Dr. Mittendorf said there was no lesion of the retina or nerve when he examined the patient.

Dr. M. A. Starr asked whether there had been any ptosis.

Dr. Weber replied in the negative.

Dr. Starr thought that a lesion lying outside of the cerebral axis, such as a syphilitic meningitis, affecting the abducens nerves at their exit between the medulla and pons, might explain the symptoms better than to suppose a lesion in the floor of the fourth ventricle affecting the nuclei themselves. Of course such a lesion would yield to syphilitic treatment, whereas he could not conceive of a nerve nucleus being destroyed and again restored. If the third nerve were involved it might be supposed that the meningitis had extended a little farther forward. He had had the privilege of seeing a case in Bamberger's wards at Vienna three years ago, in which the third, the fourth, the sixth, the seventh, and the eighth nerves on one side were paralyzed, and Bamberger made the diagnosis of lesion at the floor of the fourth ventricle, involving the nerve nuclei from above downward, especially as there were signs of atrophy in the facial muscles. The autopsy showed localized meningitis affecting these nerve trunks after their exit from the cerebral axis.

Dr. Weber again mentioned the symptoms present, and said that, so far as the oculo-motorius was concerned, there certainly had been an affection of the superior and inferior recti.

Dr. E. C. Seguin had not been convinced, from seeing the patient that evening, that there were any ataxic symptoms in the right upper extremity. The dropping of the fingers might indicate either weakness of the extensors or the loss of a certain amount of muscular sense, which might be due to a lesion situated in many places besides the pons. He was inclined to Dr. Starr's view. The discussion seemed to indicate the vanity of theoretical pathology.

Dr. Spitzka said that in his crude way he had always regarded muscular-sense disturbance as a factor of ataxia, and he believed authorities generally would so consider it.

Dr. Seguin said that Erb had recently described a case in which there was ataxia, but in which all sorts of sensation were perfect.

Dr. Spitzka said that had nothing to do with the question. Ataxia was of different kinds—cerebellar, spinal, due to ordinary contact, to muscle sense, space sense, and co-ordinatory disturbances, sometimes singly, sometimes combined; but muscular-sense disturbance was mentioned in the definitions of ataxia by our best authorities, and he would like Dr. Seguin or any one to formulate a general definition of ataxia which should declare muscular-sense disturbance not to be a factor. It was precisely because there was muscular-sense disturbance that he believed the lesion to be pontile. The interolivary layer happened to run in the deep part of the pons, in those levels where the cranial-nerve symptoms of the case in question were possible. He had shown, if any one case was conclusive, that this layer was the muscular-sense tract, and the case agreed with others of its kind. There was a combination of slight paresis with the muscular-sense disturbance which was almost characteristic of certain pons diseases, it requiring but an extension of the lesion across the deep transverse pons fibers to involve the pyramidal-tract bundles. With regard to the suggestion of a meningitis, it did not seem to him to harmonize either with theory or with experience. It was true that the affection of both abducens nerves might be accounted for in that way, but there were other symptoms which the supposed lesion must accommodate. How to account for the arm symptoms on this ground he did not know. There were too many important nerves near the hypoglossal, whose function was intact, to account for the dysarthria on the ground of meningitis. Besides, there was no true paresis of the hypoglossal. The intrinsic movements under its control were well executed, and there was no evidence of either nuclear or peripheral hypoglossal palsy; in other words, it was some higher tract—the speech tract—that was involved. We knew that this ran somewhere in the pons, near the rhaphe, whereby another nerve -the fifth—was affected in its decussation, thus accounting for the bilateral disturbance of face sensation. But the strongest objection to the meningitis theory was that it would have us believe it possible that the third pair could be diseased so totally in its extra-cerebral course—or intra-cerebral, for that matter—as to cause total paralysis of ocular motion, without any affection of the pupil, the accommodation, or the levator palpebræ. He had never heard of such a case, did not think there was one reported, and did not believe it possible. If there were no other reason for suspecting pons disease, one would, in his opinion, be constituted by the character of the ocular paralysis. But, in addition, we had the almost pathognomonic combination of paresis and ataxia. True, Dr. Seguin called it muscular-sense disturbance, which it was undoubtedly, with this difference in interpretation and definition—that he said it was not ataxia, whereas the speaker considered it to be such.

Dr. Starr thought that the abducens nuclei could not be involved, together with the interolivary layer, without affecting the formatio reticularis, which ought to have caused sensory symptoms if affected.

Dr. Spitzka said the difficulty seemed to be that Dr. Starr had only one particular level of the pons in mind—one not necessarily involved in the case, inasmuch as not the nuclei of the abducentes, but co-ordinating tracts, were supposed to be at fault. Even allowing that the lesion was in the level spoken of by Dr. Starr, the difficulty he discovered did not seem to be as he had stated it. That no symptoms referable to the formatio reticularis were present could constitute no objection so long as the function of that part which lay between the rhaphe and the abducens roots was unknown. The abducens roots, however, skirted and partly perforated the interolivary layer, and so far it was possible to have coincident abducens and muscular-sense disturbance; the real difficulty in this case would be to account for the double involvement of the abducens without bilateral involvement of the interolivary layer. As he understood Dr. Weber when he presented the case to him, he supposed the lesion to lie in the anterior third of the pons, with a dorso-mesad, and possibly caudad, extension to near the ventricular floor. Here the altitude of the tegumentum was extremely low. A comparatively small lesion might involve the interolivary division of the lemniscus—he meant its continuation, the rhaphe, with its trigeminal decussation, the posterior longitudinal fasciculi, the pyramidal tract slightly, and the speech, according to either Raymond's and Artaud's or the other theories. The advantage of this explanation over the others offered was that it required

the smallest lesion to harmonize with the symptoms, while grave objections could be urged against every other theory, particularly the one which would locate the lesion as a meningitis involving peripheral nerves. He repeated that, until the inconsistencies of the oculo-motor paralysis were explained away, insuperable obstacles opposed the meningitis theory. Possibly Dr. Weber's reference to the voluntary control of single ocular muscles might lead to misapprehension. No ocular muscle was capable of isolated movement under voluntary effort, but groups of them were. There was a ready-made co-ordinated mechanism of which the posterior fasciculus was probably the important mediator, which regulated the co-ordination of both globes, and it was here where the trouble lay.

A Contribution to the Study of Landry's Ascending Paralysis.—Dr. Leonard Weber read a paper on this subject and said: It was in 1859 that Landry had described a few cases of ascending paraplegia with negative post-mortem results as regarded the spinal cord, to which he gave the name of *paralysie ascendante aiguë*, and in the same year Kussmaul had reported two rapidly fatal cases of spinal paralysis in which the post-mortem appearance of the cord was apparently normal. Petit-fils's attempt to classify Landry's ascending paralysis among the varieties of polio-myelitis anterior acuta or subacuta had been repeated quite recently by Immermann, but, in the light of later researches, and of the negative results of autopsies made by Westphal, his theory was hardly tenable. Another and perhaps less objectionable theory was that of Roger, who believed that many cases of the favorable form of Landry's paralysis were really polyneuritis acuta, of infectious or other origin, in which the spinal cord was either not at all or only secondarily affected. In an article in "L'Encéphale," No. 2, 1885, this writer had instanced the clinical picture presented in many affections of the spinal nerves, particularly in polyneuritis, in which the symptoms were very similar to those of disease of the medulla spinalis. In cases of simultaneous peripheral and spinal affection a correct diagnosis was of course difficult, but, although we had hitherto, said Roger, paid almost exclusive attention to the central lesions, the course of the disease often bore evidence to the fact that the lesion ascended from the periphery to the center. And he maintained that not only many cases of Landry's paralysis, but also Duchenne's *paralysie générale spinale subaiguë*, and *paralysie diffuse*, belong in the category of peripheral nervous affections.

Dr. Weber then gave Roger's description of the usual course of the disease, and said, regarding the ætiology, that we were still in the dark. Westphal laid much stress upon infection, and Roger drew attention to the frequent coincidence of polyneuritis and tuberculosis. Erb had said, so late as 1879, that cases of progressive polyneuritis ought not to be mistaken for acute ascending paralysis, since the differential diagnosis was sufficiently established by the sharp pains, the anæsthesia and paralysis limited to the affected nerves, and their rapid loss of electrical excitability.

On the strength of these recent observations he thought it might be justifiable to speak of two forms of acute ascending paralysis—the well-characterized spinal and the less well-known peripheral forms. Acute ascending spinal paralysis was characterized clinically by motor paralysis, beginning usually in the lower extremities and advancing with some rapidity to the trunk and upper extremities. The bladder and rectum were but little affected, sensation was nearly normal, and the affected muscles did not waste much, nor suffer any change in their electrical excitability. More or less fever might be present, and death from asphyxia was not a very unusual termination. No cord lesions were found at the autopsy. Landry's paralysis was more common in men than in women, and occurred with greatest frequency between the ages of twenty and forty years. It had been thought by Landry, Westphal, Roger, and others that infection, of an unknown character as yet, might be the real determining cause of the disease, and it was significant to note that in some carefully made autopsies changes similar to those occurring in other infectious diseases had been found in the liver, spleen, lymphatic glands, and intestinal follicles. In the fatal cases death might occur at a period of the disease varying from two or three days to three or four weeks, but the average duration seemed to be from eight to twelve days. When recovery ensued, improvement began usually within a few days after the disease had been fully developed, restoration occurring first in the parts last affected, and progressing very slowly.

Some cases of polio-myelitis anterior subacuta simulated acute ascending paralysis very closely, and it might not be until the development of atrophy and the loss of electrical excitability that we could be certain of the presence of anatomical lesions in the spinal cord. But a well-marked case of polio-myelitis anterior acuta was not progressive, did not attack the medulla oblongata, and did not lead directly to a fatal termination; the loss of faradaic excitability and the muscular atrophy developed rapidly. In very light cases a doubt might arise in diagnosis. In acute central and infectious myelitis we always found fever, marked sensory disturbances, early loss of all the reflexes, paralysis of the sphincter, diminished faradaic excitability, bed-sores, and a rapidly fatal termination. Certain forms of spinal syphilis closely resembled Landry's paralysis, and the diagnosis could often be determined only by the history of the case and the positive results of specific treatment. The prognosis of acute ascending paralysis was always serious, as it was impossible to tell at the beginning whether a case would result in recovery or death. Antisyphilitic treatment had given doubtful results, but better had been obtained from the wet pack or warm baths followed by cold affusions. Of remedies, the best seemed to be iodide of potassium and ergot. The application of a continuous current along the spine had been recommended by Erb.

The author then related the following case, which had been observed by himself: On December 20, 1880, he had been called to see J. H., a butcher, thirty-one years of age, of apparently good constitution, with no hereditary taint, who denied syphilis. In early life he had suffered often from intermittent fever. At the age of twenty-one he went to work in a barometer factory, and after some time he began to grow weak, and had occasional slight tremor and frequent vertigo, but no salivation or other sign of mercurial poisoning. These troubles increased, so that he was compelled to give up this work after four years. He then spent four years in the West, and returned home, in good health, two years ago. About three weeks before he was seen by Dr. Weber his horse ran away with him in his open cart, and he was obliged to exert all of his strength to control the animal. He received no apparent injury or concussion, but felt tired and ill all the afternoon. The next day he kept about with difficulty, and the day following felt somewhat ill and had slight fever, and, after some days of paræsthetic feelings, such as numbness and tingling creeping up from the fingers, gradually lost the use of both arms; and two weeks later, after similar sensations proceeding from the toes upward, the lower extremities became also paraplegic. No paresis of the sphincters was noticed then or at any subsequent time. The stools were retarded. The intercostals and other muscles of the trunk remained intact, and there were no symptoms indicating involvement of the medulla oblongata; but the patient felt some pain along the spine, and continued to have pain and numbness here and there in the extremities. Up to the time of Dr. Weber's visit the patient had not been examined with special care. He found him still unable to do more than move his limbs slightly

while in bed; he could neither stand nor walk, nor had he the power to grasp any object firmly. Cutaneous sensation appeared to be normal, but the patellar and Achilles-tendon reflexes were absent. The limbs were not wasted, and the muscles responded to electrical stimulus. The pulse and temperature were normal, and an examination of the urine gave negative results. The slight improvement of the paralysis, noticeable to the patient at the beginning of the fourth week, had not progressed any further. Ascending myelitis and polio-myelitis were excluded, and the diagnosis was made of ascending paralysis—Landry's. It being impossible to carry out at his home a systematic course of electrical treatment with massage and warm baths, which seemed to be indicated, the patient was removed to Roosevelt Hospital, where the late Dr. Evetzky became interested in the case. He agreed with Dr. Weber as to the probable nature of the disease, and also looked upon the chances of recovery as good. The patient was discharged, cured, on the thirtieth day, and was soon able to resume his occupation. He called at Dr. Weber's office October 30, 1885. at which time he appeared in fair health, could walk briskly and firmly, and said he was well able to attend to his business, but required more sleep than he had five or six years ago. He had occasional backache, but no lancinating pains; the bowels were somewhat constipated; the urine was normal; the patellar-tendon reflex was totally abolished on both sides; and he could not stand very well on one foot when the eyes were closed. The pupils were normal. There were no sensory disturbances and no paræsthesia.

Dr. Weber then related briefly two cases recently reported by Sorgenfrey and H. Mietks, in which there was early loss of the patellar and Achilles-tendon reflexes, but in which, as opposed to his own case, the reflexes returned after the complete recovery of the patients. He also mentioned a case of Immermann's in which the diagnosis had wavered between anterior polio-myelitis and Landry's paralysis, and in which, at the autopsy, there was found recent inflammation of the anterior horns in the cervical, dorsal, and lumbar regions of the cord. It was this case which had led Immermann to conclude, with Petitfils, that both these clinical pictures might be due to the same morbid process, differing only in degree.

Dr. E. C. Seguin had not seen a case of Landry's disease, but he had always had a strong suspicion that there was a great similarity, if not identity, between that disease and polio-myelitis acuta. The mere matter of ascension did not seem to him to be of so great importance in the diagnosis. The views which, when a pupil, he had heard Brown-Séquard frequently express with regard to the ascension of spinal symptoms had always seemed to him very reasonable. They were that ascension of symptoms might be apparent when they did not represent any ascending lesion in the cord; they were due to a change in the depth of the lesion in the cord. Suppose, theoretically, a case of paralysis of the arms, with subsequent paralysis of the legs; it was not at all necessary to suppose a descending lesion in order to explain the descending symptoms; a change in the depth of a lesion which extended but a little way up and down the cord could account for the descent of the symptoms. In the same way we could account for ascending symptoms without supposing an ascending lesion in the cord. Many authors laid stress upon the value of negative symptoms in the diagnosis of Landry's paralysis—such as absence of degenerative reaction and muscular atrophy; but it was equally true that in many cases of polio-myelitis these symptoms were retarded. He regarded Immermann's case as instructive, inasmuch as it showed the similarity, if not the identity, of the two diseases; the difference might be in the exact location or in the virulence of the affection.

Dr. Grace Peckham described the symptoms in the case of a girl sixteen years of age, whom she had seen only once, and made a diagnosis of acute polio-myelitis following exposure by sitting on a rock. She had given a favorable prognosis. The case was reported by Dr. Rockwell before the American Neurological Society in June last as one of transverse myelitis, with recovery. Considerable discussion had followed with regard to the nature of the disease.

Dr. Sachs thought that, while Immermann might entertain the idea that the pathological process in Landry's disease and polio-myelitis was the same, he did not suppose that he believed the lesions to be identical in localization. While the question of infectious origin had not been demonstrated in either acute myelitis or Landry's disease, the speaker thought it deserved investigation.

Dr. Weber closed the discussion, reviewing the differential diagnosis between Landry's paralysis and polio-myelitis anterior acuta.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of November 5, 1885.

The President, Dr. B. F. Baer, in the Chair;
Dr. W. H. H. Githens, Secretary.

Lymphatic Leukæmia in Childhood.—Dr. J. M. Keating read a paper on this subject, and related a case, which he prefaced with some remarks on the blood in children in health, and also its diseases, briefly reviewing the literature of the subject.

Oophorectomy for Ovaralgia.—Dr. William Goodell exhibited the ovaries from two cases of oöphorectomy with the following histories: When the first patient, an unmarried woman aged thirty, first consulted him she weighed two hundred and thirty-six pounds, but at the same time she was very weak and could barely walk. She suffered excessive pain at her catamenial periods, which appeared only at long intervals. She had cataleptic and hystero-epileptic fits, and complained of very constant and acute ovarian pains. Her urine was passed but once a day, and was attended with much suffering. The womb was enlarged and the ovaries were very tender indeed, but nothing else abnormal was discovered. Assafœtida and the bromides were prescribed in large doses, and she was advised to try the rest treatment. Fourteen months later she was again brought by her physician to consult Dr. Goodell. She then weighed only one hundred and twenty pounds, having lost one hundred and sixteen pounds, and she was in every respect worse, her ovarian pains being constant and very acute, and requiring large doses of morphia to control them. Her catamenia had not appeared for about four months, and tonics seemed to have no effect whatever on her. Her physician was compelled to be in constant attendance on her, and was liable to be summoned at any hour of the day or night to give her a hypodermic injection. Masturbation was suspected, but she always denied practicing this habit. Nothing further could be done than the operation of oöphorectomy, which was accordingly performed a few days later at the hospital of the University. The ovaries were found much enlarged from cystic and interstitial degeneration, but there were no evidences of peritonitis or of cellulitis which had been suspected. A corpus luteum existed in one ovary. A rectal hæmorrhage or vicarious menstruation having taken place a few days before the operation, her ovarian pains at once left her; she needed but very few doses of opium, which was given by rectal suppositories. Her convalescence was prompt, and she returned home in less than four weeks free from all pain, and in a fair way to get perfectly well. The case was a typical

one of the advantages of oöphorectomy, yet he (Dr. Goodell) thought that the operation was being performed altogether too frequently.

Oophorectomy for Bleeding Fibroid of the Womb.—In the second case the lady was thirty-seven years of age and had been married eleven years. She gave birth to a child about seven years ago, and since then has had one premature birth at seven months and one miscarriage. She first noticed an abdominal tumor nine years ago, but her catamenia began to be free some time before this. Late in the year 1881 the catamenia began to be excessive. As nothing served to check them, early in the following year Dr. Goodell was consulted. He found multiple fibroids of the womb. Six tumors could be readily made out, of which two seemed peduneulated. The sound gave a measurement of 4·5 inches. Under ergot and ammonium chloride the patient improved for several months, then the menorrhagia became worse, and finally a dribbling of blood kept up between the periods. In May of the present year she again consulted Dr. Goodell. She had been dribbling continuously from January, and was much reduced in strength. Being a brunette, she exhibited the facies uterina in a most marked degree, the pigmentation being very dark and extensive. The womb now measured 7·5 inches. She was admitted into Dr. Goodell's private hospital, and on May 24th both ovaries were removed without difficulty. They were greatly enlarged by follicular degeneration, a condition which Dr. Goodell had repeatedly seen in cases of fibroid tumor. The effect of the operation on the tumor, and especially on the main one, was astonishing. After two weeks that fibroid had diminished in length nearly a hand's breadth. Her recovery was prompt, and she was sent to Atlantic City to recruit. On July 10th, just forty-seven days after the operation, she called on Dr. Goodell, who found the tumors very greatly reduced in size and the uterine cavity measuring only 3·25 inches, a diminution of 4·25 inches. This extraordinary amount of diminution, in spite of the fact that the obliteration of the ovarian blood-vessels cut off only a small portion of the blood-supply to the womb, forced upon him the conclusion that the ovaries were the important factors in inviting blood to the womb. Every successful case in which he had removed the ovaries for fibroid tumor of the womb had been followed by the menopause and by rapid diminution in the size of the tumor. But in his hands and in those of others this operation was more fatal than that of ovariotomy. During the ten months of the present year he had had twenty-five cases of ovariotomy with but one death, and that one in a lady operated on at her home, two hundred miles from Philadelphia. For simple cases of oöphorectomy the mortality should not be greater than that of ovariotomy. But, when complicated with the presence of a large or an adherent fibroid tumor, the operation was often one of great difficulty. Twice during the past year he was unable to reach the ovaries, and was compelled to abandon the operation, because in neither case was the woman willing to undergo the risk of having hysterectomy performed. Each case recovered, and while the women were under observation the tumors appreciably lessened in size, as if the shock of the exploratory incision had temporarily suspended the ovarian influences.

Dr. Montgomery was glad to hear the good results in Dr. Goodell's cases. In a few of the cases upon which he had operated the menopause did not at once occur—sometimes not for two years after the operation. In such cases the tumor did not decrease in size while menstruation continued. In the case of hysterectomy for fibroid tumors, reported by Dr. Montgomery at the last meeting, the temperature at no time exceeded 101·6°, and the patient left the hospital that day perfectly well. He preferred removal of the uterus and its appendages entire when the ovaries could not be removed in consequence of previous inflammatory changes. Ligation of blood-vessels supplying the tumor might be useful when nothing better could be done.

Dr. Baer thought that when the ovaries could be removed it was the preferable operation.

Dr. Goodell had been so uniformly successful in removing the ovaries for the cure of fibroid uterine tumors that it was his choice. He had been notified that he would be called in consultation in a case of fibroid tumor of the womb in a woman aged thirty-three years. This would be the third. He should advise removal of the ovaries. If at the time of operation that was not found possible, he should close the incision, as the other operation was very dangerous, and the patient could certainly live a few years as she was. In one case only of his oöphorectomies had the menses continued, and he thought in that case there must have been some supplementary ovarian tissue.

Ovariotomy.—Dr. Montgomery exhibited for Dr. Warder a large ovarian tumor, and related the following history: The patient was a young woman. Her menses commenced at seventeen years of age, and had always been irregular. They ceased entirely for twelve months, and at the same time the abdomen was enlarging until the tumor reached above the navel. Fluctuation was doubtful; the mass seemed quite solid, and pressed the uterus down into the pelvis. Anæsthesia did not relax the abdominal wall, and diagnosis was doubtful. An exploratory incision, showing the pearly tint of an ovarian tumor, made it sure. Nothing would pass through the trocar, but some of the jelly-like contents of the tumor escaped beside it and passed into the abdomen. The large cyst was filled with small cysts. The patient did well for one week, then the pulse became rapid; but she had since been doing well, and was then rapidly recovering.

Dr. Goodell thought the danger from the escape into the abdomen of cyst-contents was overrated.

Dr. Baer said that in the early stage of ovarian tumors metrorrhagia was sometimes present; sometimes the menses were entirely absent. He should like to hear from the society some reason for this inexplicable difference.

Dr. Goodell had observed the same facts, but could throw no light upon it.

Dr. Montgomery remarked that in this case both ovaries had undergone cystic degeneration. The second ovary contained numerous small cysts.

Dr. Baer inquired about the treatment of the second ovary.

Dr. Montgomery replied that it was removed.

Some Uses of Cocaine in Gynæcology.—Dr. C. H. Thomas read a paper on this subject, in which he related some personal experiences in the use of the drug in various gynæcological operations. He recommended it highly for local anæsthesia, and did not think that any toxic effects were likely to be produced even by a saturated solution.

Miscellany.

The International Medical Congress.—At the semi-annual meeting of the Camden County, N. J., Medical Society, held November 10th, the following resolutions were unanimously adopted:

Resolved, That this society approves of the action of the American Medical Association in enlarging the Committee of Arrangements for the Ninth International Medical Congress in 1887.

Resolved, That the rules regulating the membership and business of

the Congress, adopted by the Committee of Arrangements at the meeting in New York, September 3d and 4th, and the transference of the future management of the Congress to an executive committee, composed of the President of the Congress, the Secretary-General, the Treasurer, the Chairman of the Finance Committee, and the Presidents of Sections, be considered by this society sufficient to silence criticism and enlist the sympathies and support of the profession throughout the United States.

Resolved, That the Secretary be instructed to forward copies of these resolutions to the county medical societies of New Jersey.

The Present System of appointing Medical Examiners in Massachusetts.—At a meeting of the Boston Society for Medical Improvement, held November 23d, Dr. W. C. B. Fifield read a paper in which he alluded to the old coroner system still in vogue in most of the States, and the cause of its abolition in Massachusetts—the unfitness of most of the appointees by reason of ignorance, whereby the course of justice was impeded, and great and unnecessary expense was entailed upon the State. But, he asked, was the new system of medical examiners so great an improvement as had reasonably been expected? It was not, because in many cases political and social influence led to the appointments. He cited instances in which, on account of the ignorance of the examiners, innocent persons had languished in jail and been put to great expense. He alluded also to ridiculous reports of causes of death. To protect the State, and save the expense of unnecessary inquests, it had recently been ordered that a medical expert should be employed in every case where an autopsy was made. What was the remedy? An examination by a commission, to make sure that the appointees were properly qualified, that honest men, of integrity and ripe judgment, should hold these offices. In every county the medical examiner should submit his report to a chief medical examiner, and then, together with the latter's supplementary report, it should be passed upon by a commission of three, amply paid and selected for their special fitness—all this before any case went to a district attorney.

In the discussion, Dr. G. K. Sabine took the ground that in country districts it was impossible to secure men of the high attainments demanded by Dr. Fifield. The expenses allowed were meager, and the State discouraged autopsies on account of the expense involved. After an autopsy, the medical examiners lost days of time in attendance at court at $1.30 a day. If a body had to be disinterred, all expenses of disinterment and re-interment had to be borne by the examiner. The office was laborious and ill-paid.

Dr. Bowditch moved a further discussion at a specified time, the medical examiners to be invited to be present, and that a committee of three be appointed to report on the proper mode of appointment. The motion was carried, and the Chairman appointed Dr. C. D. Homans, Dr. R. H. Fitz, and Dr. G. B. Shattuck to constitute the committee.

Dr. Draper, one of the examiners for Suffolk County, thought that no great fault could be found with the present board of examiners. Many of those now serving were or had been officers of the Massachusetts Medical Society; they understood their duties fully, and performed them without fear or favor. Dr. R. H. Fitz also spoke in defense of the present system.

THERAPEUTICAL NOTES.

Ditana Digitifolia as a Galactagogue.—Professor Giurleo, of Naples (cited in "Nouveaux remèdes"), speaks in decided terms of the galactagogue powers of this Mexican plant, alleging that it not only increases the secretion of milk, but causes it to take place in cases where it has been altogether lacking. It must be used continuously. The author gives the following formula for making a "galactophorous syrup":

Flowers and leaves of *Ditana digitifolia*		4½ ounces;
Sulphuric ether, 85 per cent. alcohol,	each	7½ "

To be kept over a water-bath for two hours, in a strong and well-stopped flask, and a tincture made by displacement. The portion of the plant which remains in the digester is then to be exhausted with 4 pints of water, in which 10¾ pounds of sugar are to be dissolved. Strain, and add 8 ounces of glycerin, and, finally, the ethereo-alcoholic tincture obtained by the first operation. Two or three tablespoonfuls of this syrup, diluted with a pint of water or infusion of chamomile, are to be taken daily.

The Pharmaceutical and Therapeutical Uses of Algin.—Mr. Watson Smith ("Jour. of the Soc. of Chem. Industry"; "Nouveaux remèdes") calls the attention of pharmacists and physicians to a new product, *algin*, discovered by Stanford. It is the residual product of the wet way of obtaining iodine from certain marine *Algæ*, being a nitrogenous principle closely resembling albumin, except in not being coagulated by heat. It forms perfectly definite *alginates* with metals. The alkaline and earthy-alkaline alginates are soluble, but the others are insoluble. The double alginates are easy of preparation, and almost all of them are very soluble. Besides possessing many curious chemical properties, giving promise of extensive applicability in pharmaceutical and other processes, algin has a notable alimentary value, and may be advantageously substituted for gum arabic in the preparation of a great number of dietetic and medicinal products.

Salicylate of Sodium in Supra-orbital and Infra-orbital Neuralgia.—Devlezersky and Finkelstein ("Wratsch"; "Rev. méd.") report cases which they think tend to show an ætiological connection between articular rheumatism and hemicrania and other neuralgias. Theirs were cases of hemicrania. Trivus has extended the treatment to neuralgia of the ophthalmic branch of the trigeminus, and reports three cases in which salicylate of sodium, given in doses of thirty grains at the onset of the pain, promptly caused the disappearance of the latter.

Formic Acid as an Antiseptic.—Schulz ("Dtsch. med. Wchnschrift."; "Ctrlbl. f. klin. Med.") commends this substance highly as an antiseptic. He has found very weak solutions effectual in preventing the decomposition of organic substances, and, although he speaks cautiously on this point, he thinks that their use is not likely to entail unpleasant effects.

Cocaine as a Remedy for Seasickness.—Mr. A. J. Duffield writes to the "Medical Times and Gazette" as follows: "If a layman's experience be of any worth, let me say that twenty years ago, when returning home from Peru, I brought with me some fifty pounds weight of fresh leaves of the cucu, and proceeded to experiment on some miserable fellow-passengers, who were suffering from seasickness, by means of a straw-colored decoction of these leaves. They were all adults—ladies, priests, and Peruvian poets. Every one of the patients fell asleep on drinking a large breakfast-cupful of my tea. They were all cured. But, on changing from the Pacific to the Caribbean Sea, the malady again attacked the priests and the poets—the women were not attacked—and again a single cup of cucu-tea had the same effect as before. Much, of course, depends on the leaves being freshly gathered."

Lime in the Treatment of Bronchial Catarrh.—Trastour ("Union méd.") recommends the following mixture:

Iodide of calcium	75 grains;
Lime-water	3 ounces;
Distilled water	12 "

A soupspoonful should be taken at the beginning of the two principal meals, in a glass of wine and water or in milk, and the use of the preparation should be continued for a long time, together with frequent counter-irritation and the repeated use of laxatives and balsamics. In case of asthma-like oppression, antispasmodics and calmatives will be needed, especially morphine.

The Administration of Antipyrine.—After a number of trials, M. Dumolard ("Lyon méd.") gives the preference to the following formula:

Antipyrine		20 parts;
Jamaica rum		30 "
Syrup, Water,	each	150 "

In typhoid fever, he gives a teaspoonful three times a day.

Diaphoretic Boluses.—A contributor to the "Union médicale" gives the following formula:

Sublimed and washed sulphur, Powdered bitartrate of potassium,	each	30 grains;
Powdered gum guaiacum		15 "
Syrup		q. s.

Divide into four boluses. All to be taken in the course of a day.

Original Communications.

UNILATERAL HALLUCINATIONS.*

BY WILLIAM A. HAMMOND, M. D., LL. D.

THE fact that hallucinations of sight and of hearing may be unilateral—that is, perceived by one visual or auditory center only—has long been known, though the subject has not even at this day attracted so great a degree of attention as it appears to me to require. Several writers have, however, considered the matter from a more or less philosophical standpoint, and have brought forward interesting cases in support of the views to which they have given their adhesion.

The first reference to the fact that hallucinations may be one-sided that has come under my notice is made by Calmet,† who describes the fright experienced by a gentleman who, passing some time in a haunted house, heard a voice in one ear—the left—which came from a corner of a closet and seemed to him to be about a foot above his head. This voice spoke to him very distinctly during the space of half a *miserere*, and ordered him, *theeing* and *thouing* him, to do some one particular thing which he was recommended to keep secret.

Calmeil ‡ alludes to the fact that some persons, the subjects of hallucinations of hearing, declare that the sounds are heard first in one ear, and then in the other, or exclusively in the right or left ear.

Baillarger # cites two cases of hallucinations of hearing occurring in but one ear. In the first of these, a woman, who was under the delusion that she was being taken to a cemetery, imagined that she heard a mysterious voice encouragiug her and telling her not to be afraid. In the other, a woman, affected with religious monomania, perceived in the right ear the sound of celestial music, which caused in her the highest degree of mental exaltation. Baillarger does not refer to one-sided visual hallucinatious.

Michéa,‖ who had previously written an excellent monograph △ on hallucinations in which, however, he did not consider those of a unilateral character, refers to them specifically in his subsequent work, and attempts an explanation of their *rationale*. He says:

"In the fantastic or subjective perception which constitutes the phenomena of hallucination the mind experiences a modification identical with that which takes place in the normal or objective perception. The false representation, the deceitful appearance, of which he has conscience, seems to it to be the result only of an exterior impression produced simultaneously on the two symmetrical or homologous portions of a sensorial apparatus. The attention is directed to the imaginary body, and not to the instruments by which the impression is produced. The mind interprets as single the double action of the sensorial organs that receive and transmit the impression of the fantastic image and by which it is brought to the consciousness and understanding. Nevertheless, it is not always thus. In certain cases the mind can be affected in such a manner that it perecives an imaginary object in the same way that it perceives a real body, the impression of which is effected on one alone of its two symmetrical and homologous portions; in a word, although always the same so far as regards characteristics and form, an hallucination may sometimes lose its unity of correspondence and be doubled and dichotomized, so to speak, relative to one single sensorial apparatus."

In accordance with this view, Michéa gave to the erroneous perceptions in question the designation of *divided hallucinations*.

Schroeder van der Kolk * cites a case, the only one, as he says, within his experience, in which the hallucination occurred in one ear. A poor woman complained to him that she was continually persecuted by the devil, who let loose at her all sorts of blasphemies, and indeed all the worse the more she exerted herself not to attend to them, but often also when she was talking and active. She had already been to a clergyman to have him exorcise the devil before she came under Schroeder van der Kolk's observation. On his asking her in which ear the devil always talked to her, she replied that it was invariably the left ear. He told her that her disorder was due to an affection of the ear that sometimes occurred.

Dr. Alexander Robertson,† in an interesting monograph, cites several cases of unilateral hallucinations occurring especially with the subjects of alcoholism. According to him, they are more frequent on the left than on the right side. He regards them as being the result of an independent action of the two hemispheres.

Dr. E. Régis ‡ enters at some length into the history of the subject, and adduces several cases in support of the view that unilateral hallucinations are always due to some derangement of the sensorial apparatus—the eye or the ear—on one side. His attention was first attracted to the subject by the case of a patient who heard himself abused in opprobrious terms, but only in the right ear. He was able to induce these hallucinations at will by closing the left ear and concentrating his attention on some particular idea, when very soon this idea would be expressed vocally to him in the right ear. This patient had been affected since he was twelve years old with a purulent otorrhœa, localized in the right ear, due to chronic catarrh of the cavity of the tympanum. A case cited by Pick sustained his view, and the others occurred in his own experience, both as regarded the eye and ear.

‡ "Des hallucinations unilaterales." "L'Encéphale," t. i, 1881, p. 43.

An exceedingly interesting form of unilateral hallucinations is that in which erroneous impressions different in character occur on either side. M. Magnan,* at the meeting of the Medical Congress in Rouen in 1883, read a paper on this form of the affection, the patients having had hallucinations in both ears, occurring simultaneously, but opposed to each other in the nature of the impressions communicated. One patient heard through one ear—always the same—threats and abusive language, which gave him ideas of persecution, while through the other ear the perception was of flattering words, and others of a character calculated to excite in him ambitious delirium, and this antagonism of sensorial auditory impressions was maintained without change during the whole course of his disease. M. Magnan reported four cases of the kind occurring in his own experience. In one the painful impressions came through the right ear, while the pleasant ones were produced on the left side. In the three others this relation was reversed. He regards these cases as affording a new proof of the functional independence of the two cerebral hemispheres, and as presenting a great analogy with the facts obtained by experimentation with certain hysterical subjects.

Of course, as is well known, the sense of touch can be the seat of unilateral hallucinations just as it is readily and normally affected by actual impressions. So far as concerns the present subject of inquiry, such derangements are of no moment, as they originate ordinarily from subjective irritations. Sometimes, however, especially in hysterical and hypnotized persons, they may have a central origin. M. Dumont-Pallier† had a patient in La Pitié whom he hypnotized, and in whom he could determine at will anæsthesia, hyperæsthia, or sensorial delirium alternately in one half of the body and the other. One of the cerebral hemispheres, it is stated, appeared to preserve its power to act while the other was deprived of all activity. By other experimental combinations he could bring the two hemispheres into simultaneous action, but in an opposite way. Thus, the patient being in the unconsciousness of hypnotism, he could, by whispering in one ear words conveying sad ideas, give to one half of the countenance the expression of pain, while, by suggesting cheerful words in the other ear, the corresponding side of the face showed satisfaction.

I have given this short *résumé* of the subject mainly for the purpose of showing the state of the inquiry at this time, and not with the idea of submitting anything like a complete history of the researches and observations made. In the next place I have to bring forward my own cases, and to make such remarks upon them as they may appear to require.

So far as I am aware, no case of unilateral illusions has yet been reported. One case of the kind has come under my notice, and, though the subject of illusions is not under direct consideration, its relations with the present inquiry are so intimate that it seems proper to refer to it here with somewhat more of amplitude than I gave to it when I first brought it forward,* nearly three years ago:

Case I.—A gentleman, in good general health, contracted the illusion that the ticking of a clock on the mantel-piece consisted of articulate words. At first he only had this erroneous perception at night after he went to bed, but in a few weeks the ticking of any clock sounded to him like human speech. There was no uniformity either of the tone or of the language employed, but sometimes a particular phrase would be repeated hundreds of times. As soon as he got beyond the range of the sound from the clock the words were no longer heard.

Generally the expressions were in the form of commands. For instance, if at dinner, they would be "Eat no soup," "Drink no wine," or "Eat your soup," "Drink some wine," and so on. One day he made the discovery that if he closed the right ear firmly the illusion disappeared, but if the left ear was closed the words were still distinctly heard. It was, hence, clear that the center for hearing on the right side was the one affected, and that that on the left side was normal. On neither side was there the slightest impairment of the capacity for hearing other words. A watch would be readily heard to tick at the distance of three feet from either ear.

These false impressions were not by any means unpleasant to him; on the contrary, he was rather inclined to attend to them and to amuse himself with suggesting new phrases for the clock to simulate. He did not allow himself to be deceived with the idea of regarding them as realities, but, though he strenuously resisted their acceptance, he began, after a time, to be influenced by them to the extent of acting upon them as guides, though he tried to conceal the circumstance. When, for instance, asked whether or not he was going to the theatre that evening, he would reply in a nonchalant way to the effect that he had not thought about the matter; and then, after a little while, when he thought the matter forgotten, he would saunter toward where the clock stood and shortly afterward give his answer either affirmatively or negatively, according to the words conveyed to him by the clock. Eventually he put clocks into every room in his house and proposed to be governed altogether by the directions they gave him, not, as he said, from any belief that the ticks were real words, but because there was some influence, spiritual or other, that caused them to seem like words to him.

During the whole time that this case was under notice there was no change in the unilateral character of the illusion nor in its distinctness. At this time the condition remains unaltered. The sounds made by the clock have all the appearance of words spoken into the right ear, while to the left ear they possess only their normal characteristics. Yet, though he is guided by them, he does not for a moment regard them as words. His intellect is free from any delusion of fact, though he is superstitious enough to accept them as conveying to him indications as to how he should act.

Case II.—This case is also referred to in my "Treatise on Insanity." A young lady of good mental development but of delicate physical organization was for several months almost constantly troubled with apparitions of various kinds of faces, which she saw no matter where she turned her eyes. She had, while looking through her father's library a few weeks before they first appeared, come across a book containing many engrav-

* "A Treatise on Insanity in its Medical Relations," New York, 1883, p. 297.

ings of Greek and Roman masks, and these had made a great impression upon her. The pale faces beset her on all sides. Sometimes they would peep at her from around the corners of the streets as she was driving or walking. Again she would see them coming out of the shelves in the shops she visited, and again they would start up from the street just before her. They never passed out of her range of vision suddenly, but gradually faded away without changing their positions. Some of them she saw with one eye and some with the other, for if she shut either eye they decreased in number, about half of them disappearing; and if she closed both eyes they all vanished for a little while, though generally in either case they reappeared in a short time, but less distinctly. On opening the eyes, a new set appeared. They were of all colors and nationalities, and a good many were of the same description as the masks of the ancients, being of various degrees and character of grotesqueness and hideousness. She never saw them after dark except in well-lighted rooms or other places. The gaslight of the streets was not sufficient to develop them, but the electric light brought them out very distinctly. By repeating the experiment of Sir David Brewster—pressing on the outside of the globe of either eye so as to produce temporary strabismus—she could make any face appear double; but this was only when it had been visible for several minutes. A newly appearing one she could not duplicate in this way. There was no derangement of the vision of any other kind, and no abnormal ophthalmological appearances.

The peculiar features of this case are that the hallucinatory images were divided between the two eyes, part being seen with one and part with the other, showing, therefore, the distinctness and divisibility of the action of the two visual centers, and the fact that the stimulus of a strong light was necessary in order that they should be developed. The circumstance that by pressing on one eyeball so as to throw it out of its parallelism with the other any image was duplicated showed the permanence of the impressions made upon the retinæ—impressions that must necessarily have been transmitted from within and projected outward.

Case III.—A young man received a severe blow on the head just above the left ear. A few weeks subsequently—while engaged at his business, that of a salesman in a large mercantile establishment—he saw a large black cat sitting on the floor immediately before him. He had no doubt of the reality of the occurrence, and for several minutes wondered where the animal could have come from. At last he made a step toward where the cat was apparently sitting, and was surprised to find that the image remained as far from him as before. He then recognized the fact of the falsity of the perception. After this the cat seemed to follow him wherever he went, and sometimes appeared to jump on his lap or shoulder. His sense of touch was never deceived.

Being possessed of a considerable degree of intelligence, he had, by observation and experiment, settled several interesting points to his satisfaction. Thus, he found that the image was always larger and more distinct in the evening than soon after getting out of bed in the morning. Occasionally at this latter time it was entirely absent, but not often. Again, it was always clearer, larger, and apparently nearer to him when he suffered from pain at the seat of the injury, as he did in paroxysms several times a day. When he was free from pain the image disappeared when he shut his eyes, but when the paroxysms were present he saw it just as well when his eyes were closed as when they were open. Pressing on either eyeball so as to destroy the parallelism of the visual axes did not cause the production of two images, and then he made the discovery, by alternately shutting the eyes, that the hallucination only existed on the side corresponding to that on which he had been injured.

In this case there were no abnormal ophthalmological appearances, nor any impairment of the faculty of vision in either eye. That there was serious brain lesion involving, probably, the left optic thalamus, I have no doubt. I was also of the opinion that there had been a fracture of the inner table of the skull at the point at which the blow had been received, and proposed trephining. He, however, declined to submit to the operation, and I finally lost sight of him.

Case IV.—A lady, about fifty years of age, became the subject of a most malignant persecution through anonymous letters which were sent to her in large number and from various parts of the country. The outrage had gone on, however, for several weeks before there was any other result than intense annoyance. But she finally began to worry greatly in regard to the source of the abusive communications, endeavoring to represent to her mind the man or woman guilty of the indecencies of which she was the victim. In this she was not successful. In fact, she could not determine whether the sender was a man or a woman, much less bring before her mind's eye his or her image. One day, however, as she lay in bed with a sick headache, her mind reverted to the question that had so often disturbed her—"Who was the person that sent her the anonymous letters?" Happening to look in the direction of the large bay-window that filled up nearly the whole front of the room, she saw a man and a woman standing in the opening.

For the moment she did not doubt the reality of the appearances, but as she raised herself in bed to look at them better she was astounded to perceive that they slowly faded out of sight—dissolved, as it were, so gradually that they scarcely seemed to get less distinct. She got up, dressed herself, and did not see the images again for several days.

But at last they made their appearance (this time while she was at the dinner-table), and presenting exactly the same aspect in every respect as they had at first. After that she saw them several times in the course of a month, and then they disappeared never to return again.

The most curious circumstance about the hallucination was that the man was perceived with the right and the woman with the left eye. Thus, if she closed the right eye she saw only the woman; and if she shut the left eye the man only was visible. If she had, by moving actively about the room, caused them to disappear, she could often bring them back by lying down on a bed with her head rather low. If, on these occasions, she kept the right eye closed, it was the woman only that appeared; and, if she opened only the left eye, she saw but the one image, that of the man. Again, if she had in this manner brought back one image, and then endeavored, by opening the other eye, to cause the other one to appear, it was several minutes, generally, before she succeeded, and thus for a time only one image was present.

Nothing, it appears to me, could be more confirmatory of the case of the independent action of the two visual centers than such hallucinations.

And, indeed, it appears to me that unilateral false perceptions of the kind in question afford strong evidence of the correctness of the theory originally proposed by Wigan,*

* "The Duality of the Mind," London, 1844.

but since his time adopted by many others, that there are in fact two brains, the two hemispheres having independent though similar functions, ordinarily acting together, though capable of isolated and even different action. Wigan had no facts of this character to allege in favor of his theory of the duality of the mind, for which, nevertheless, he has addueed many striking proofs and convineing arguments, and toward the truth of which science seems to be tending.

Régis, in the memoir to which I have previously referred, advanees the opinion, in which he is apparently borne out by the cases he has adduced, that unilateral hallucinations are due to disease or derangement of the organ of speeial sense involved. That this is not always the ease I am very sure. In none of the instanees I have cited was there any ocular or auditory trouble. It is diffieult to see what connection can exist between disease of the eye or ear and an hallucination existing in the corresponding side. For, if such disease caused a unilateral hallucination, we should expect bilateral hallucinations to be the result of disease of both eyes or ears.

I do not believe that hallueinations are caused by lesions of the organs of special sense, but that they are produced by disease or disorder of the eentral organ of perception, probably of the optic thalamus, and that sneh erroneous sensorial impressions, when limited to one side, are evidenee that the visual, auditory, or other sensorial center, as the ease may be, of the corresponding side, is the starting-point.

EXCISION OF THE TARSAL BONES.*

By CHARLES T. POORE, M. D.,
SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN.

Disease of the tarsal bones is not an uneommon oeeurrence among children who apply for admission into hospitals. The following paper is based upon the cases of nine patients operated upon at St. Mary's Free Hospital for Children. Although there is nothing very noteworthy in any of the cases taken individually, yet, when taken together, they form a group from whieh one may draw a few praetieal deductions.

The following plan of operation was followed in all but one case, to which referenee will be made further on: After rendering the limb bloodless by an Esmareh bandage, if the os calcis is to be removed, an ineision is made from a point corresponding to the inner edge of the tendo Achillis and about an ineh above its insertion, outward and then forward on the outer aspeet of the foot to a point midway between the external malleolus and the proximal end of the fifth metatarsal bone, the incision being made direetly down to the bone. The only tendons denuded are the tendo Achillis and that of the peronæus longus where it passes over the lateral surface of the os calcis. No vessel of any size requiring ligature is divided. The incision will be found to afford plenty of room. The periosteum is then divided and separated from the bone as far as possible with an elevator; it will then be found that the bone can be removed either as a whole or in pieces, the ligaments being divided as they present themselves. After removing all the bone and well washing out the cavity left by the operation, the constricting bandage is removed, and any bleeding points are secured. The edges of the ineision are brought together with silver wire, except at the posterior part of the wound, which is left for a drainage-tube. I use silver wire because, in my experience, it is often neeessary to hold the parts in eoaptation longer than can be done with catgut. The foot is usually put up in a tin leg-splint, with a foot-piece at right angles to the leg. The cavity left after the removal of the bone is in some cases swabbed out with chloride of zinc, in others dusted over with iodoform. None were put up in a permanent dressing. The following is an abstract of the eases:

Case I.—F. M., three years of age, came to the hospital in 1874. She was an unhealthy-looking child. There was a large sinus, from which there was a considerable discharge, situated upon the dorsal aspect of the right foot, over the upper border of the cuboid bone. There was also disease of the first metacarpal bone of the left hand. In September, 1874, the patient was etherized, and the disease was found to be confined to the os calcis. This was freely gouged so as to remove all diseased bone. The portion left seemed hard, and was supposed to be healthy. In January, 1875, as the wound did not close, more diseased bone was removed. In April, as the foot was no better, an incision was made by splitting the tendo Achillis and then extending the incision forward upon the plantar surface of the foot, so as to afford room to remove the remains of the os calcis. The cavity thus left was stuffed with lint. The wound gradually filled up, and she was discharged with her foot in good condition, the heel somewhat flattened and with a deep cavity behind.

November 1, 1885, eleven years after the operation. Upon examination, it was found that the foot was in good condition. There had been no return of disease, no pain about the foot, and the child walked with but a very slight limp, scarcely perceptible. The heel, where there had been a deep depression at the time of her discharge, had now filled out, so that the point of excision was represented by a mere line occupying the posterior rather than the plantar aspect of the foot. The contour of the heel had filled out. There was an obliteration of the plantar arch. I do not think that there had been any reproduction of bone.

Case II.—M. D., aged three years and a half, had had disease of the os calcis for some time. The bone had been gouged twice before the patient came to the hospital, but without any permanent relief. He was a healthy-looking boy. There was a sinus on the external aspect of the foot over the os calcis, through which diseased bone could be detected. In February, 1879, the old line of incision was reopened. There was found a sinus in the os calcis leading to a cavity in which was a loose piece of bone of about the size of a filbert. The walls of this cavity were smooth and hard. The necrosed bone was removed and the wound closed, in the expectation that, the cause of irritation being removed, recovery would take place; but after a time the parts assumed the same condition that had existed before the operation. In May the bone was excised. It was found harder than normal. After the last operation the patient made a good recovery, and was discharged, walking well. He has not been seen since his discharge from the hospital.

Case III.—M. R., aged seven years, was admitted in February, 1879. Three months previous she began to complain of pain in the heel of the right foot. It then began to swell, and three weeks before she came under observation an abscess opened

* Read before the New York Surgical Society, November 24, 1885.

posteriorly, and had continued to discharge since. Diseased bone could be detected with the probe. In March the os calcis was removed. It was found entirely diseased. She was discharged from the hospital in June, able to walk well. She was seen November 20, 1885. She then walked well, with scarcely a limp, had had no pain, and the old line of incision had not reopened. About one year ago, five years after she left the hospital, an abscess formed on the dorsal aspect of the foot, and has continued to discharge ever since. There is now a sinus at this point. The patient seems healthy, and experiences no inconvenience from the foot. I presume there is diseased bone. There has been some reproduction of the os calcis.

Case IV.—Sarah J., four years before admission, received a cut on the plantar surface of her right foot from a piece of glass. The wound had never closed. Three years ago some diseased bone had been removed, and since then several small pieces had come away. In November, 1879, the os calcis was removed. The bone was extensively diseased. In February she was discharged, able to walk well. A week after her discharge she was brought to the hospital with a superficial abscess about the point of operation, caused, it was said, by walking with a badly fitting shoe. She was sent home in a few days. In May, 1883, her friend reported that she had had no further trouble, and that she walked well.

Case V.—C. R., ten years old, came to the hospital in March, 1881, with the following history: Six months before, without any known cause, a swelling had appeared at the back of the heel; an abscess had formed and opened, and had continued to discharge ever since. The os calcis was removed, and was found to be much diseased. He was sent home in June with a useful foot. He was seen November 20, 1885. There has been no change in the foot since he left the hospital; he can walk well, with but little, if any, limp, and is now employed as an errand boy in an apothecary's shop. There is, however, limited motion at the ankle joint. There does not appear to have been any new bone formed.

Case VI.—Peter H., an unhealthy-looking boy, about six years of age, was admitted in September, 1881. He had disease of the right os calcis, and carious bone in various portions of his body. In October the os calcis was removed. He did well for a time, then his foot began to swell, the old line of incision opened, and he was in a worse condition than before the operation. Other tarsal bones became involved in the disease. The bones were gouged, but with no improvement. In March, 1883, Syme's amputation was performed. The flap did well for a time, but finally sinuses began to form, and he was removed from the hospital. On examining the parts after their removal, there was found considerable reproduction of bone.

Case VII.—K. A., three years of age, was admitted in January, 1882, with disease of the os calcis of some duration. The bone was removed in February, 1882. She was discharged April 20th, with the wound all closed, and able to walk well. Nothing has been heard from her since she left the hospital.

Case VIII.—Joseph M., six years of age, came under observation in February, 1882, with a history of disease of the bones of the left foot of some duration. There was a sinus over the astragalus through which carious bone could be detected. The foot was much swollen. On March 20, 1882, the sinus over the astragalus was enlarged, and that bone removed by gouging. It was then found that the anterior portion of the os calcis was diseased. The anterior two thirds were removed through an incision on the external aspect of the foot, leaving the posterior portion of that bone. The foot did well for a time, the anterior wound closing, but a sinus persisted posteriorly. In October, as the portion of the os calcis left was evidently diseased, it was removed. After this the wound closed, and he was discharged with a sound and useful foot. He has not been heard from since.

Case IX.—Edward L., two years and a half old, was admitted in September, 1882, with an extensive swelling on either side of the left ankle joint. Fluctuation was marked. He had been lame for some months. The abscess in the ankle joint was opened under ether, and the lower end of the tibia and the articular surface of the astragalus were found denuded of cartilage. The diseased bone was gouged and the joint drained. The abscess continued to discharge for some time, and then the sinus closed about the ankle joint, but a new opening formed over the anterior surface of the astragalus in front of the ankle joint. Subsequently the astragalus and the os calcis, which were found diseased, were removed. At the time of the operation there was no disease about the end of the tibia, and the bone was well covered. The patient was discharged from the hospital with a useful foot, all sinuses being closed. November 19, 1885, he was seen at the hospital. He has had no trouble with the foot since. Can walk well with a slight limp. The end of the tibia occupies a lower plane than that of the sound limb, so that the ankle joint is depressed. There has been some reproduction of bone.

Of these nine cases the os calcis was alone removed in seven, the os calcis and astragalus were removed in two. A useful foot was obtained in eight, and in one amputation had to be performed. In but one of these eight cases has there been any return of the disease in the other tarsal bones, and in this not until five years after the operation. All but three of the patients have been seen or heard from within the past year, and in all, with but one exception, has the foot continued in good condition, and the patient been able to walk and be about with other children without any inconvenience except a slight limp. In all there has been an obliteration of the plantar arch, with a tendency to walk upon the inner border of the foot. All complain that the inner side of the shoe is worn out first, but there has been no pain.

In regard to a partial removing or gouging of the os calcis for disease, my own experience has not been flattering. Although a faithful trial of this procedure was made in four cases, no permanent cure was obtained, and only after total extirpation of the diseased bone did the sinus close. In one case the bone had been operated upon three years before the patient's admission, with no apparent benefit.

Case II, where there existed a sinus leading into the center of the os calcis, in which was imprisoned a loose piece of dead bone, seemed very favorable for such an operation, yet it failed to stop the disease, and a total excision of the bone had finally to be performed. In another case the posterior third of the os calcis was left, as it was apparently healthy, but recovery did not take place until this, too, had been removed. I am well aware that others have obtained good results from partial excision or gouging, but perhaps it was in older subjects and under more favorable circumstances. My own experience is entirely opposed to a partial operation in children. Perhaps one cause of the want of success in these cases is the fact that the bone was sclerosed and incapable of filling up the cavity left by gouging.

I have never made a resection of the ankle joint in

children, although I have seen some cases of disease of this articulation—I mean in which the lower end of the tibia and fibula was extensively diseased. The patients made a good recovery.

THE PROBLEM OF ACCLIMATIZATION.*

By ISAAC HULL PLATT, M. D., Brooklyn,

ASSOCIATE PHYSICIAN TO THE DEPARTMENT OF THE DISEASES OF CHEST, ST. MARY'S GENERAL HOSPITAL, AND TO THE HOSPITAL FOR NERVOUS AND MENTAL DISEASES, BROOKLYN; MEMBER OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS, THE BROOKLYN PATHOLOGICAL SOCIETY, ETC.

Although the subject of acclimatization is a long-vexed one, and has led to much discussion from the various standpoints of the biologist, the anthropologist, and the physician, it appears to be in a very unsettled condition in the scientific mind, both as regards the limits of the changes classed under that head and the physiological laws by which they are governed.

This seems to be due, in a great measure, to the fact that the subject has never been approached in the light which the advance in the sciences of biology and anthropology in recent years is capable of affording.

While I have no new facts to offer, and no personal observations to record, it has occurred to me that a few suggestions in relation to the lines of thought by which the subject may be approached would not be out of place, nor devoid of interest to us, as students of medicine and climatology, and might, perchance, serve as a ferment in some mind more capable of the task to set in operation processes of thought and observation tending to the elucidation of the matter.

That such thought and observation are called for will be manifest to any one even glancing over the literature of the subject. While one class of writers speak of acclimatization of plants and animals as a matter of course, and of man as being the animal most capable of adaptation, others scout the idea of the human race being, in any degree whatever, subject to the modifications grouped under that head.

Mr. Alfred Russel Wallace, in the ninth edition of the "Encyclopædia Britannica," has, in his usual interesting and able way, presented the subject as it stands at present, with the arguments *pro* and *con*, but with the result of showing that we are still far from understanding the problems involved.

Mr. Wallace defines acclimatization as "the process of adaptation by which animals and plants are gradually rendered capable of surviving and flourishing in countries remote from their original habitats, or under meteorological conditions different from those which they have been used to endure, and which are at first injurious to them." The definition is important because much of the argument which has been adduced against the possibility of acclimatization will be seen to have no bearing upon the subject when brought to this test.

Many anthropologists and climatologists have denied the existence of acclimatization altogether. Knox even went so far as to assert that the white population in America and elsewhere out of Europe would die out if not replenished by immigration. Probably no one would make such an assertion at the present day; but Parkes, in his "Practical Hygiene," and Turner, in Buck's "Hygiene," deny, in a general way, the possibility of acclimatization in the human race, especially as regards malarial fevers, and they are far from standing alone in their position.

Common experience certainly seems opposed to this view. Nearly every one who has traveled has learned that, in undergoing even slight changes in atmospheric and telluric influences, slight disturbances of the system occur which pass away in a short time. It is a matter of common observation and remark that, while the natives of a region subject to any endemic disease show but slight susceptibility, new-comers fall its easiest victims, and foreigners who have been long resident enjoy comparative immunity.

The fact to which Dr. Westbrook called attention in his paper before this society last year—namely, that recent immigrants, more especially the Irish and their children, are peculiarly liable to consumption—must be a familiar one to all physicians whose practice brings them in contact with that class, and yet our fifty millions of people, probably as healthy and rapidly increasing as any in the world, are the descendants of immigrants, and a large proportion trace their ancestry to the Emerald Isle. After a few generations they show no special tendency to phthisis, certainly no more than the inhabitants of many of the old countries, including the British Islands.

Wallace, in the paper already referred to, quotes from notes furnished him by Dr. Richard Spruce, who resided many years in South America, to show the perfect acclimatization of the Spanish race in the equatorial regions of that continent. In Guayaquil and Piura, from latitude 2° to 5° south, where the mercury rarely falls below 80°, even at night, for months at a time, the white population is of Spanish descent, and of a high moral standard as regards the relations of the sexes, thus preserving it from admixture with the native races. The women are considered the finest on the Pacific coast; they are tall, handsome, healthy, and prolific; the men are large, stout, strong, and well nourished.

Dr. Spruce's notes also show examples of different portions of the same race of Indians, who have taken up their abodes in regions widely divergent in climatic conditions, and each become thoroughly adapted to its new environment. He says: "The warmth-, yet shade-loving Indian of the Amazon; the Indian of the hot, dry, treeless coasts of Peru and Guayaquil, who exposes his head to the sun with as much zest as an African negro; the Indian of the Andes, for whom no cold seems too great, who goes constantly bare-legged and often bare-headed, through whose rude straw hut the piercing wind of the *paramos* sweeps and chills the white man to the very bones—all these, in the color and texture of the skin, the hair, and other important features, are plainly of one and the same race.

"Now," he goes on to say, "there is a zone of the equatorial Andes, ranging between about 4,000 and 6,000 feet altitude, which is very desirable to cultivate, but where the red man sickens and dies. Indians taken down from the

* Read before the American Climatological Association, May 28, 1885.

Sierra get ague and dysentery; those from the plains find the temperature chilly, and are stricken down with influenza and pains in the limbs," thus showing that, while each has become acclimated to his peculiar habitat, even a partial change toward the conditions of the other branch of the race proves deleterious and in many cases fatal.

The history of the colonization of Algeria by the French is interesting and to the point. After the conquest, about 1845, continual attempts were made by the French to plant colonies there, and, for a number of years, with very little success. The mortality far exceeded the increase by births. The colonists died off, the fertility of the survivors became reduced, and it was prophesied by physicians and anthropologists that the attempt would prove a failure. After the first few years, however, the tide turned, the births exceeded the deaths in number, and the census of 1870 showed a large increase in French population, only a small proportion of which could be attributed to immigration.

Instances might be multiplied indefinitely of the adaptation of races to new surroundings, but it seems profitless in view of the fact that is now undisputed that the Aryan and Semitic races, springing from neighboring regions in southwestern Asia, have made for themselves homes and established nations in every quarter of the globe, proving conclusively that acclimatization as a race phenomenon has been co-extensive with the colonization of the greater part of the planet.

It has frequently and strenuously been denied that acclimatization can or does take place with regard to malarial and endemic fevers, and the argument to prove it is that Europeans are rapidly and fatally attacked by these fevers upon taking up their abode in the regions where they prevail. This certainly does not prove that acclimatization is impossible, but only that it is necessary, for by the definition we have seen that acclimatization is a process of gradual adaptation to influences at first injurious. If this susceptibility of new-comers did not exist there would be neither its need nor its possibility.

If we accept the modern views in biology we can not escape the conviction that acclimatization is not only a possibility, but an inevitable consequence of a change of climatic surroundings within certain limitations.

"The broadest and most complete definition of life will be," says Herbert Spencer, "the continuous adjustment of internal relations to external relations." * It is a universal principle with living organisms that within certain limitations they have the power of adaptation to their environment, and, if exposed to unaccustomed surroundings which fall short of producing such commotion as to terminate its life, the organism will, by a gradual process, undergo such functional and structural changes as to better fit it for its new environment. In fact, the biological law of adaptation is but one phase of an even more general law, for, according to Spencer, "it is a corollary from the persistence of force that any deviation effected by a disturbing cause, acting on some other member of a moving equilibrium, must (unless it altogether destroy the moving equilibrium) be eventually followed by a compensating deviation." †

* "Principles of Biology," § 30. † *Op. cit.*, § 68.

Nearly all the physical influences surrounding a human being, or any of the higher animals, are those which go to make up what we know as climate. The air he breathes, and in which he is constantly bathed; the temperature to which he is subjected; the moisture of the atmosphere, with its effect upon his cutaneous and respiratory organs; the emanations from the soil; the water he drinks; the food he eats; and the clothing he wears—are all either elements of climate or are determined by it. In fact, the climate to which he is subjected is practically co-extensive with his environment. Acclimatization is, therefore, as regards the human race and the higher animals, practically an equivalent expression with adaptation to environment which Mr. Spencer has shown is the fundamental law of biology.

Admitting, then, that acclimatization is a reality, it is evident that it will present itself in two different aspects—as a phenomenon in the life history of an individual and as affecting the races of mankind. In its ethnic aspect, it has been a concomitant of those great streams of emigration which have from prehistoric times poured out from the source of the Aryan race in the valleys of the Himalayas, ever advancing, carrying all obstacles before them, until they have overrun nearly the whole of Europe, portions of Asia and Africa, besides both Americas and Australia. In a lesser degree it has been illustrated by the career of the Jewish race, which, starting from Palestine, has wandered far and wide upon the earth, making itself homes in strange lands.

As students of climatology, and, as all physicians must be to some extent, of anthropology, this ethnic acclimatization has its interest for us, but, as practitioners, the matter of individual acclimatization is of more vital importance. Let us for a moment consider the new forces brought to bear upon the human organism by a new climate, the effect produced upon the organism, and its reaction.

Climates differ in their temperature, their humidity, the weight and density of the atmosphere, and in the degree of variation of each of these; also in the composition of the atmosphere and its impurities, and closely associated is the nature of the food and water-supply. Of course, in a paper like the present it would be impossible to analyze the effects of changes in each of these climatic elements upon the human organism, even if the physiological data were sufficiently well understood, and a mere suggestion is all that will be attempted.

As a general principle, any decided change in the climatic influences brought to bear upon the body will result in a change in the relative demand for functional activity of the various organs. The increased functional activity of one set will result in increased growth and development, while diminished activity of another set will lead to a corresponding atrophy, and in this manner a considerable amount of adaptation will be accomplished. For instance, suppose a person to go from a temperate to a hot climate. The demand upon the skin for increased work, in keeping down the body temperature, is at first greater than it is able to perform. In some manner the liver is deranged, our imperfect knowledge of the functions of that viscus not enabling us at present to say exactly how, but with the effect of caus-

ing hyperæmia and intestinal derangements. Without attempting to go minutely into the physiological changes induced by the increased temperature, certain things are evident. The relative activity of the excretory organs is deranged, greater work is called for upon the part of the skin, less is demanded from the lungs and kidneys. The call upon certain organs for work for which they are not prepared can not but result in its imperfect accomplishment, and consequent derangement of the system. But, upon the same principle that a muscle develops by increased use, or the eye or the hand becomes trained to greater skill by exercise, the organs upon which the greater demand is made must, if the organism survive the change, gradually adapt themselves to the increased activity by increased growth and development. The organs which are partially relieved of their function will undergo a corresponding structural involution, the balance of the system will be restored, and the organism adapted, so far as these disturbing elements go, to its new habitat. Accordingly, we find that in the inhabitants of hot climates the lungs and the kidneys are less developed than among the dwellers in the temperate zone, the skin and the liver more developed. In illustration of the changes wrought in the structure of the body by climatic influences, it has been shown that among the dwellers in high altitudes—for example, the Peruvians at an elevation of from 7,000 to 15,000 feet in the thin, cool atmosphere of those heights—the lungs become greatly hypertrophied and the body short and compact.*

There are many other elements in the series of changes which the body undergoes. The physiological action of heat upon the sympathetic and cerebro-spinal system of nerve-centers is first that of stimulation, followed by a secondary sedative action, which leads to diminished functional activity of the various organs considered collectively, and consequently the heat production of the body is diminished, as it should be in the course of adaptation to a tropical climate. Probably the effect produced by the climatic influences upon the nervous system has a large share in the adaptive changes. The food demanded by the tissues is of a less stimulating and less heat-producing character, less meat and fat, more fruits and vegetables. This change in an Englishman, for instance, accustomed to his roast beef and mutton-chops, will call for a training of the appetite and of the digestive and assimilative organs, and approximation to those of the herbivorous and fruit-eating animals. Much of the intestinal disturbance consequent upon residence or sojourn in hot climates is probably due to the need of adaptation in this respect. More or less change in other habits of the individual would become necessary, and would be made when experience had taught him its need.

Until the science of physiology is more fully understood, and the function of every organ and the histological changes going on therein are made a matter of more nearly exact demonstration, and the action and reaction of each organ upon every other clearly seen, we can not expect to ascertain the precise manner in which the innumerable influences which go to make up climate do their work. For the present, we must be satisfied if we can discern in them a harmony with general principles.

Turning again to the subject of race acclimatization, we find another factor of prime importance at work—namely, the principle of natural selection. By the dying off of the individuals whose vital energy is insufficient to endure the changed conditions of life, and the survival of those who have become best adapted to the change, the race would be propagated only by those individuals who, either by an accidental correspondence with the new conditions or by a process of adaptive changes, have come into harmony with them, and the progeny, inheriting the peculiarities of their parents, would continue down the generations, as race characteristics, the modifications of structure and function which render them suitable to their new habitat. That this process of race acclimatization does occur is shown by the rapid increase of the negro race in the Southern States, and by the fact that members of that race taken from temperate climates back to the tropical regions whence their ancestors came sicken and die of the same disorders as the whites who go there.*

One phenomenon has been often cited against the doctrine of acclimatization of races which, rightly considered, will be seen to be one of its most important factors. It is the fact that children of emigrants from any region to one widely differing from their own in climatic conditions are frequently deficient in vigor, especially as regards the function of reproduction, the women being sterile in many instances, and the race consequently nearly or quite dying out in the course of a few generations.

To a certain extent the power of procreation may be considered as an excess of vital power over and above that required to maintain the life of the individual; consequently, when the vital power becomes reduced by struggles with adverse surroundings, the reproductive function is the first to suffer, and, of course, if the change in climatic conditions is sufficient to extinguish it, the race will of necessity die out; but this only shows the limitation of the power of adaptation, not its non-existence; for, if the reproductive function be not extinguished but only limited, this very limitation will aid the process of natural selection by allowing the race to be propagated only from those individuals whose power to resist the injurious effects of the changed conditions has been greatest, and thus gradually bringing the race up to their standard.

Natural selection, then, has been an important factor in the changes produced in a race by change of climate. Is it not possible to regard it as taking a part even in the modifications of the individual organism? It is sometimes difficult to determine exactly what constitutes an individual. Of course it is easy enough to tell the difference between one man and two, but in some of the lower forms of life it is often a question whether an organism should be considered as an individual or as a community of individuals. Now, the body of man or any of the higher animals may be considered as a highly organized community, composed of distinct masses of protoplasm or cells generated one from another, each of which is in a sense an individual living

* D'Orbigny, "L'homme américain," i, pp. 96–113. Waitz, "Anthropology," p. 37. Walshe on "Diseases of the Lungs," 4th ed., p. 337.

* Martin on "Tropical Climates."

being, and each of which assimilates, excretes, reproduces, performs its function in the animal economy, and dies. The growth and multiplication and functional activity of these cells are dependent upon the play of molecular forces in the cells—that is to say, upon the entrance and exit of nutritive fluids into and from their interior, and the changes effected by the cells in such fluids and in their own walls.* If, therefore, we conceive of these forces being affected by the environment, as it would seem they must, it will be obvious that the law of natural selection has its part in the modifications wrought in the various organs of the body. For, if the cells going to the formation of any given organ or part of an organ differ in any degree among themselves, no matter how slight that difference may be, some of them must be better suited to the new conditions of life than others. From these, therefore, cell generation would be carried on to a greater extent than from the others, and the organs which they constitute, and the organism itself, would be correspondingly modified.

A change from a cool or temperate climate to a warmer one has been considered; other changes would operate in a similar manner. The converse, removal from a warm to a cool climate, would result in converse changes. Differences in humidity, acting upon the skin and respiratory organs in a somewhat similar way, would effect corresponding changes, and climates of wide and sudden fluctuations in regard to temperature or moisture, or both, would demand still further modifications of the organism, which would be brought about by the operation of the same laws which we have been considering.

The question of acclimatization to malarial influences is an exceedingly interesting one, but one which involves problems beyond our present power to solve. Admitting immunity from endemic malarial diseases, partial or complete, to follow long residence on the part of either an individual or a race in a region subject to their influence, we can scarcely do more than call attention to analogies between this phenomenon and certain other immunities from the injurious effects of noxious influences acquired by custom. Such is the toleration established for certain poisons —for instance, opium, arsenic, and tobacco—in those accustomed to their use. Of apparently like nature is the immunity from variola afforded by vaccination, and from various zymotic diseases by a prior attack. These are problems still awaiting solution; but, whether it shall be proved that these influences have added something to the protoplasm of the cells, or taken something from it, or produced changes in it by catalysis, or whether the changes shall be found to be in the constituents of the blood, all of which theories have been advanced to account for the phenomena, the phenomena themselves must of necessity be found to result in some manner from the changes in arrangement and composition of living matter, brought about by the new conditions to which they are exposed.

Enough has been said to show that the problem is a complicated one, but one which lies properly within the scope of physiological science. Its mastery will involve the solution of many of the most profound questions of biology—the actions of heat and cold, of dryness and moisture, upon the functions of the skin and lungs, the digestive and blood-making organs and the circulation, the kidneys, the glandular system, the cerebro-spinal and sympathetic nerve-centers, upon the action of the vaso-motor and trophic nerves, and the mechanism governing the production of animal heat, together with the reactions of the changed conditions of each of these upon the functions and structure of the organism. The influences of changes in the atmospheric pressure and consequent density upon the respiratory organs and the body in general must be considered, as well as the effect of sudden or gradual fluctuations in each of the climatic elements. The effects wrought upon the organism by the presence of diseased germs, the influence of changes in food and water, in clothing and habits of life, must all be considered.

It is evident, and becoming more fully recognized every day, that in the manifold conditions grouped under the term climate we have at our command, not one, but a host of hygienic and therapeutic agents, capable of exerting upon the human body influences potent for good if rightly used, but, like all other therapeutic agents, powerful for harm when used improperly. Hence it must be evident that any progress made in this branch of climatology will be of inestimable value, not only in the treatment of disease, but in the determination of the forces which are to go to the improvement and development of the human race.

DISCUSSION.

Dr. Shattuck thought the paper was extremely interesting, and suggested some points for discussion. Regarding acclimatization of the negro in the Southern States, he was reminded of what had been said by Dr. Miller in conversation last year. Dr. Miller said that consumption, which was formerly almost unknown among the negroes while they were slaves, had, at least in large districts of the South, become extremely prevalent, and was increasing in frequency and fatality. Of course the climate remained essentially the same. The explanation seemed to be that under slavery the negroes were all well cared for, their masters employed good physicians, and it was to their interest to look after the health of their slaves, and to provide them with enough to eat, sufficient clothes, and suitable dwellings. In other words, the negroes were entirely removed from the operation of the law of the struggle for existence and the survival of the fittest. At present their welfare was nobody's interest but their own, practically; there was nobody to look after them, and they were subject to the law before named. This seemed to be a sufficient explanation of the spread of consumption among this class of the Southern population. The speaker could not understand how any one could deny that there was such a thing as acclimatization. If one would simply take a walk in England and then in one of the New England cities he would no longer have any question about it. The New England population was originally of perfectly pure English blood, and the contrast in the appearance of the inhabitants of the two countries at present was certainly great. Something had brought about the change.

Dr. Westbrook wished to ask a question regarding the negro race of this country. He had understood the author of the paper to say it was increasing. He had recently seen some statistics going to show that it was not increasing. The mortality among the negroes in various parts of the States was very great, and the writer in question thought there was a tendency for the

* Carpenter's "Physiology," 8th ed., p. 437.

race to die out. Probably the reason was to be found in what Dr. Platt had stated concerning the negro's present and former condition.

Dr. Platt said he had not made a study of the increase of the negro race in this country, but the census showed a very great increase from 1870 to 1880. He had noticed recently in one of our magazines an article intended to quiet apprehension created by some alarmists that the whole nation was in danger of becoming Africanized by the rapid increase in the negro race, and the author showed that the great increase was only apparent, from the fact that the census of 1880 was much more complete than previous ones.

AN ACCOUNT OF A SUIT FOR DAMAGES

IN A CASE OF ALLEGED INJURY BY A BLOW ON THE EAR.

By GORHAM BACON, M. D.,

and D. B. ST. JOHN ROOSA, M. D., LL. D.

In this case both of the writers were called as witnesses, and, for the sake of convenience, we will give the circumstances relating to it according to our respective testimony.

Dr. Bacon's account of his experience in the case immediately follows:

I was consulted, about April 1, 1885, by Mr. X., who said that a suit for assault and battery with injury to the hearing was to be begun against him shortly in the courts, and he asked me if I would examine the child, whose hearing was said to have been injured by the blow, if permission were granted by the plaintiff. Having consented to do so, Mr. X. said that his lawyer would call in a few days and give the particulars of the case. The defendant's lawyer having written to the plaintiff's counsel, and not having had any reply, he made an appointment with me to call at the plaintiff's house and request an examination of the child whose hearing was said to have been damaged. On our arrival at the house, we found that the father of the child was out of the city, and had an opportunity of questioning the boy, who seemed to hear conversation addressed to him in rather a loud tone of voice. He seemed to be about eight years of age, poorly nourished, with a decided nasal twang to his voice, and breathed with the mouth wide open. His mother came in and said that her husband, Mr. Y., was out of town, but would return in a few days, and that he was perfectly willing to have a doctor examine the child, provided he were present himself at the time.

On the return of Mr. Y. to the city, he called at my office and made an appointment to bring his boy. He called on the appointed day, but without the boy, whom he was unable to bring, as he had contracted a severe cold in his head and he was in bed. He was obliged to shout at him in order to make him hear. He said he would call in a few days, which he did, but, as the boy was still unable to come with him, he asked that the proposed examination be made at his house. April 18th I called to see the child, Master Y. He was still confined to the house and was so hard of hearing that I had to shout to make him hear. Both parents were present and told me that Mrs. Y. and children passed the summer of 1883 at a hotel on the Long Island shore, Mr. Y. being absent, however, in Europe. The assault on the child by Mr. X., who, with his wife and children, was also staying at the same hotel, occurred during a week in August while Mrs. Y. was away and the children were left in charge of a colored nurse, who witnessed the blow. Mr. Y.'s children were in the habit of playing with those of Mr. X., and they said that the cause of the assault was a dispute between one of Mr. X.'s children and Master Y. over the possession of a butterfly. Mr. Y. said that his child was a year older than Mr. X.'s and much brighter. Mr. X. became very angry on hearing of the trouble between the children, and at first was going to cane Master Y., but instead brutally assaulted the boy, about an hour after the dispute, hitting him severely across the left side of the face and ear with his hand. Mrs. Y. returned from her trip in about a week after this and learned of the trouble from the colored nurse. After the blow, the nurse said that the boy complained immediately of pain about the left ear and of a buzzing noise. He was put to bed, and remained there that day and the following. The ear broke, but soon stopped running, and, when Mrs. Y. saw him on her return, the boy seemed to feel badly and still complained of a buzzing noise in his ear. The nurse applied some vaseline to the ear and side of his face. The boy played about after he got up from bed, but did not seem so bright as before. No doctor saw the child at this time. The parents stated, further, that the child had never had any aural disease previously, and that his hearing had always been good. He had measles and whooping-cough when three or four years old. He had always been a healthy child. They deny any hereditary tendency to deafness on the child's part, although I noticed, in talking with his father, that the parent's hearing was not perfect. Master Y. was in the habit of bathing and diving in the salt water during the summer. The noise in the ear, complained of after the blow, troubled him at times till about the middle of September, since which time he has not complained of any noise in either ear. In the early fall Mrs. Y. went with the boy to the mountains, where his hearing seemed to improve, but grew worse again on returning to New York. In October she took the boy to her family physician, who treated him for a short time. Since the occurrence of the blow Master Y. has been subject to head colds, and whenever he has had one of these colds his hearing has been affected; "it has gone to his ears." He hears better on dry, clear days. He breathes with mouth open during sleep. As the deafness seemed to increase, the parents took him to see Dr. Rounds, at the Ophthalmic Hospital, in March, 1884. He is under the doctor's care at present, and has been since the first visit in March. The hearing has been gradually improving of late, and two weeks ago he heard quite well. He has been confined to the house during the past week on account of a severe cold in the head, and the deafness has been very marked. There has been a discharge from the left ear, but none from the right one. He has had pain in both ears, but more in the right one. Mrs. Y. applied an onion to each ear and dropped camphorated oil into both canals.

Examination.—Master Y., aged eight, anæmic, poorly nourished, has a dazed or stupid appearance; breaths with mouth open. On closing the mouth, he breathes with difficulty through the nose. He has chronic naso-pharyngeal catarrh with hypertrophy of the tissues in the nasal passages. The left nasal passage is more obstructed than the right. The septum nasi deviates to the left side. He has chronic pharyngitis with thickening of the palatal folds; tonsils not enlarged; uvula elongated.

Right membrana tympani congested and swollen; epidermal layer sodden and coming off; also from the inner end of the canal. Left membrana tympani presents almost the same appearances, although less congested. No perforation seen in either ear.

Hearing distance, watch, right ear, contact; left ear, contact. When very close to him he hears loud voice in the right ear and very loud voice in the left ear. Tuning-fork, when vibrating and placed on the vertex cranii and teeth, heard with

the same intensity in each ear. The bony conduction is much better than the aërial.

After inflation by Politzer's method the hearing distance was much improved, and the difference in the hearing power between the two ears was then much less marked. By means of the diagnostic tube it was perceived that air passed more readily through the right than through the left Eustachian tube.

At the trial both parents told their side of the story substantially as I have given it, with one exception, however, that after the blow they said the boy had pain in the ear and side of the face; but they did not mention any buzzing noise or discharge from the ear at the time.

The colored nurse who had charge of Master Y. in the absence of the parents testified that Mr. X. made a sudden attack on the boy while he was at her side; that he struck him such a severe blow that the boy fell over against her, and that he was ill for several days and complained of pain about his ear. The plaintiff produced four or five witnesses who testified that they had frequent opportunities of observing Master Y. up to the summer of 1883, when he left town, and that they had observed no difficulty with his hearing. Among these were his two school-teachers and a lady at whose house he was frequently engaged in playing with the children.

The defendant, Mr. X., testified that he saw Master Y. at the hotel on the Long Island shore in July, 1883. He was boarding there at the time for a few months with his wife and three children. He went back and forth occasionally to New York. His oldest child was four years old, his second two years and a half, and the youngest only eighteen months. There were thirty or forty guests at the hotel. He said, further, that a few days preceding the occurrence for which this action was brought he saw Master Y. annoy his youngest child and attack his children. He used obscene language to them. He saw him run down his youngest child on the lawn. Two days after he saw Master Y. walk up to his second youngest, who was standing under a tree playing with a toy express-wagon, and snatch the wagon away from him with such force as to throw him down and injure him. He then said to the boy, "If you hurt my child again I shall be obliged to punish you." On the day of the occurrence of slapping the boy Mr. X. testified that he was sitting reading on the hotel piazza. A lawn was in front of it about four hundred feet wide, on which were a number of trees and bushes. About 11 A. M. he suddenly heard screams from the opposite end of the lawn, and immediately afterward the nurse who had his child in charge came running toward him alone and called him. He ran to the child and found him lying on the ground and panting and very blue in the face. He had been ill and had been carried out to the place on the lawn. Mr. X. carried him up stairs, and, while doing so, saw Master Y. running from the spot. The witness further said that he looked then for Master Y., but, not finding him, returned to the piazza to read. About half an hour after, while still on the piazza together with his wife and several other ladies, the colored nurse who had charge of Master Y. came up leading the boy by the hand and said, "Here is ——." Mr. X. then said, "——, have I not told you that if you hurt my children again I would punish you?" He did not reply, and, thinking that the nurse had brought him up to be punished, Mr. X. with the right hand gave him a slap on the left cheek, which did not stir him an inch. The nurse did not say anything about hurting the child. The boy walked away with the nurse and was crying a little. The defendant further testified that he did it simply to protect his children; that he had no malice, but rather pitied the boy. He saw him coming into dinner that day, saw him repeatedly in the afternoon the next day, and every day as long as he remained at the hotel. He did not notice any difference in his actions or condition after that day, except that he did not go near his children again.

The nurse having charge of Mr. X.'s children testified that Master Y. was in the habit of annoying the defendant's children; she told of the quarrel between the children over the possession of the butterfly, how Master Y. kicked her child, and how she called to Mr. X. for help.

Mrs. X. and other ladies on the piazza at the time testified that they saw Mr. X. carry his child in when hurt, and that he did not injure Master Y. at all by the slap he gave him. They further said that the boy was playing around as usual all of that day, and they noticed no difference in the child's actions; noticed no mark about the face or ear. The wife of the proprietor of the hotel said that she examined the boy's face soon after the slap and saw no swelling of any kind; that he sat beside her at dinner that day and ate and seemed as well as ever.

A gentleman who was in the habit of being frequently with the children at the hotel said that before the boy was slapped he noticed that Master Y. at times did not hear well, and he had to repeat his questions to him; that the boy was in the habit of bathing and remaining in the water a long time.

The foregoing is substantially the testimony that was presented in regard to the nature of the blow, although not a verbatim report. The following testimony is from the stenographer's notes, but with some verbal omissions:

Testimony of Dr. William T. White, a witness sworn on behalf of the plaintiff.—I have attended Mr. Y.'s family. I am not a specialist in diseases of the ear. In my practice as a physician I have treated diseases of the ear. I treated Master Y. in October, 1883, for trouble with the ear. There was an abscess, and I treated him five days and then dismissed him.

Cross-examination.—I mean by an abscess a discharge of pus. I can't tell from which ear, but there was a discharge of pus.

Re-direct examination.—I can not tell the primary cause of the pus; there was inflammation, of course, preceding the formation of pus. A severe blow on the ear might create inflammation of the drum of the ear.

Re-cross-examination.—I can't tell what I did for the ear. I treated it on general principles. I examined the ear, but not with Politzer's inflation, etc. I found there was an abscess there, or running of pus from the ear, and I treated it as I did any other abscess. I never was called in afterward that I recollect.

Testimony of Dr. W. E. Rounds, a witness sworn on behalf of the plaintiff.—I have made a special study of diseases of the ear. I am connected with the New York Ophthalmic Hospital as surgeon. I became acquainted with this boy (Master Y.) in April, 1884. From that time to the present I have seen the boy on an average once a week. I have treated him for deafness in both ears, I believe more especially the right ear. Both ears were affected. He has catarrhal inflammation of the ear-drum. I have known inflammation of the drum to result from a blow. There is inflammation of the drum.

Q. Suppose a boy had been suffering from catarrh in the head and was struck a severe blow on the ear, in what way would that affect his hearing?

A. It might set up an inflammation of the drum, I think such an inflammation as I observed in this boy. I could not positively swear that that condition was due to a blow, although I would say that it might be.

Q. Assuming that the boy's hearing was perfect up to the time he was struck, and from that time complaint was made as to defect in his hearing, and, when he came to you, you found him in the condition that you have stated, and suppose you had been told that prior to the summer of 1883 this boy's hearing

had been apparently perfect, and that then he had received a severe blow on the right ear, and that succeeding that you had, in April, 1884, found the boy's hearing in the condition that you found it, to what would you attribute his condition?

A. Unless there were evidence, I could not in fairness answer that. I could attribute it to anything which had produced the inflammation. If there were evidence of a blow there, I might attribute it to a blow. I did not find any such evidence of a blow. A blow might set up an inflammation which would continue and produce deafness. I believe inflammation might exist as the result of a blow without my finding, seven months after the blow had been struck, the traces of a blow itself.

Cross-examination.—I found this boy suffering in April, 1884, with naso-pharyngeal catarrh and an unnaturally opaque condition of the drum-membrane. I have seen such conditions produced by a catarrh. Catarrh is an affection of the middle ear, the drum. Catarrh is an inflammation of the mucous membrane wherever you find it. In connection with the middle ear, it is not always an inflammation of the Eustachian tubes; it may be of the drum-cavity, and sometimes of the nasal passages also. When I examined this boy I found that he did have a catarrhal condition of the nose, pharynx, and ear. I think that condition had existed for some time: I couldn't say how long. It was a chronic condition. It had existed, I should say, for a number of months. I should say in his case it had been standing eighteen months or a year; I wouldn't say positively. Some cases become chronic sooner than others. That condition may come from other causes than a blow, but I have known of cases of inflammation of the drum being set up by a blow upon the ear. An inflammation of the drum must be catarrhal. The most common causes of a catarrhal condition of the ear are sudden atmospheric changes, colds in the head, and anything which produces an inflammation of the mucous membrane. I recorded this case in my note-book at the hospital as one of chronic catarrh of the middle ear. Of course, I couldn't see the drum-cavity. The drum-membrane had an unnaturally thickened or opaque condition and was drawn in, pushed in farther than normal. That is all I remember about the case. I think that catarrh might be produced by a blow under certain circumstances. I think a blow upon the ear might produce an inflammation of the middle ear. I don't say that it could produce a catarrhal condition of the Eustachian tubes and the nasal passages. I have recorded that the right ear was more inflamed than the left, that the hearing was more diminished in the right ear than in the left. He is deaf in both ears. Inflammation in the ear opposite to the side of the face on which a person was struck probably could not be produced by a blow upon the side of the face opposite to the ear in which the inflammation appears. There was inflammation in both ears. A blow might produce an acute inflammation in the ear that was already affected. Inflammation in the right ear-drum would not of necessity affect the left ear; I don't think it would naturally; one would not of necessity depend upon the other. If I had a case in which there was a catarrh of both ears and the trouble was acute in one, I could readily see how that trouble could have been aggravated by a blow upon the ear on the side where the blow or slap had been given. In this case it was in the right ear. All that I remember about the case, when I saw it at first, is as it is reported in the records. As nearly as I can remember, the deafness then was greater on the right side; and as to the inflammatory condition, there was no apparent difference between the ears. It was a chronic condition. I have treated him off and on since then for catarrhal deafness.

Re-direct Examination.—I think a blow would be more likely to set up an inflammation where a person was suffering from chronic cold in the head and his nasal organs were affected than if the ear was healthy; it would be more likely to aggravate the disease. I can't swear from memory in which particular ear this deafness was. I can only swear to my impression.

Testimony of Dr. Gorham Bacon, a witness sworn on behalf of the defendant.—I devote my attention to diseases of the ear. I am surgeon at the New York Eye and Ear Infirmary. I made an examination of Master Y. two weeks ago. (The testimony in regard to the boy's condition, as given on the witness stand, is similar to that already given at the beginning of this paper.)

Catarrhal deafness is a disease of the middle ear and the Eustachian tubes. (The witness here explained on the model presented to him the location of the different parts of the ear.)

Chronic naso-pharyngeal catarrh affects the middle ear by means of the Eustachian tube, which is lined by mucous membrane, as well as the nose and posterior part of the pharynx. The Eustachian tube (one on either side) opens into the side of the naso-pharynx or back part of the throat, so that catarrhal inflammation affecting the nose and naso-pharynx proceeds up the tube to the middle ear. The Eustachian tube allows a proper ventilation of air to the middle ear, so that the pressure on both sides of the drum-membrane may be equal. When the Eustachian tube is closed by catarrhal inflammation and the parts are swollen, the air does not properly enter the Eustachian tube, and, consequently, the pressure of the atmosphere pushes the drum-membrane inward and interferes with the hearing. The ventilation is also communicated through the nasal passages. A healthy patient should breathe with the mouth closed, and the air should pass through the nose and Eustachian tube into the middle ear. A catarrhal inflammation, when the patient is not able to breathe through the nose, and he breathes through the mouth, interferes with the proper ventilation of the middle ear, so that changes take place there and the hearing is interfered with in that way. I found in my examination of this boy that there was a closure of the Eustachian tube of each ear, and, by forcing air through the tubes into the middle ears, and in this way removing the obstruction of mucus, that the patient heard very much better; it improved the hearing very materially. That introduction of air was by Politzer's method of inflation. I inflated both ears, and, by means of a tube, I connected my ear with the ear of the patient on either side, and heard in each middle ear the bubbling sound characteristic of the presence of mucus in the middle ear. I tested the boy's hearing with regard to the condition of the internal ear by means of the tuning-fork.

By vibrating a tuning-fork and then holding it just a little in front of the ear, and afterward placing it back of the ear on the bone, if the patient hears the tuning-fork louder when it is placed on the bone than when it is held directly in front of the ear—that is, when a patient is deaf—it shows that the trouble is in the middle ear, and not in the labyrinth or nerve. This boy heard the tuning-fork better by bone conduction in each ear, showing that the trouble in each ear was dependent upon middle-ear disease, and that the nerve was not affected. I couldn't tell how long this chronic catarrh of the middle ear had existed. I could only say that in this child's case it had probably existed several years on account of the obstruction and thickening of the mucous membrane in the nasal passages and naso-pharynx. An opaque condition of the membrane, accompanied with inflammation, is an indication of chronic catarrh. The usual symptoms of rupture of the drum-membrane include sharp pain at the time; there may or may not be some bleeding from the ear; there usually is. The patient is apt to be dizzy, and often vomits; is sick at the stomach, has a staggering gait, is unable to walk, and has a ringing noise in the ear. I should say that a slap upon the face of a child such as this boy was two years ago, which was not sufficient to move him from

a perpendicular line or throw him over, would not in any way affect his hearing. Catarrhal deafness can not be produced by a blow. Mouth-breathing is invariably a sign of the presence of catarrh when a patient habitually breathes with the mouth open. A slap or blow upon one side of the face could not produce deafness on the other side of the head unless it produced concussion of both nerves, and, from an examination of the patient, there was no trouble with that part of the ear. The indications of catarrhal deafness were precisely the same in both middle ears. Repeated immersion of the body in water during a series of days or weeks in one predisposed to catarrhal deafness increases it, and, in some cases where the water enters the auditory canal so that it passes down against the drum-membrane, it produces inflammation of the drum-membrane and middle ear. In summer we have a great many patients at our hospital that suffer from inflammation of the middle and external ears from sea-bathing and diving. If a slap or blow is given a boy on the first of August, and is followed by a discharge of pus in the latter part of October, it could not be attributed to the blow unless the boy had a chronic discharge from the ear from the time of the blow. Otherwise there would be no connection between the two. An abscess in the ear usually means a discharge from the external ear. The discharge may come from the middle ear, but, in order to come from there, there must be mucus in the discharge, as the lining of the external ear is not mucous membrane, and, consequently, unless there is rupture of the drum-membrane, there can not be a discharge of mucus. A very frequent cause of a discharge of pus from the ear is the presence of a boil or small abscess in the external auditory canal—that is, in that portion of the ear outside of the drum-membrane. Catarrh is a frequent cause of deafness in children, especially in the climate of New York, where the changes in the weather are so frequent.

Cross-examination.—Mr. Y. was to have brought the boy to my office for an examination, but he said that the boy had been confined to the house on account of a recent cold in the head or catarrhal attack, and gave me permission to examine him at his house. Mr. X. had asked me to make the examination.

Q. Be kind enough to tell us if that was not the reason why you were employed, because the defendant doubted that there was any trouble with the boy's hearing?

A. He had his doubts. I don't remember Mr. X. saying that he didn't believe there was any trouble with the boy's hearing. He had a letter of introduction to me, and asked me if I would examine the boy and find out exactly what was the matter with him—whether there was any deafness. On the first occasion when I called with Mr. ——, Mr. X.'s lawyer, Mr. Y. was not at home. I did not then make an examination. I saw the boy playing in front of the house in the area. I did not speak to him then.

Q. In which ear is there the greater trouble?

A. There is no difference, so far as I know. There was an affection of both ears—a catarrhal affection. When I made my first examination, I found that the deafness was greater on the left side. After forcing air, however, through both Eustachian tubes into the middle ears, the deafness on both sides was very nearly equal; it was a little greater on the left side, owing to there being more catarrhal trouble on the left side of the nose, which would account for that. In nasal catarrh there are usually changes in the middle ear; there may not be any appreciable deafness, but, on testing the patient with the tests that we have for hearing, we find that the hearing very often is greatly impaired.

Q. You know that the hearing of any two people is not the same?

A. In the normal ear there is very little difference in the hearing distance. Patients very often don't know that they are deaf, the same way that they don't know that the eyesight is not good.

Q. You would call a man that didn't know he was deaf, scientifically deaf?

A. I would, although he thought he was not deaf. A person afflicted with chronic catarrh in the head is apt to have his hearing affected, although you can not tell without an examination of the ear. This boy had chronic catarrh in the head, nose, and back part of the throat. I do not know that a person's hearing is more sensitive when he is afflicted with a chronic catarrh of the head, and that a blow upon such a person is more liable to interfere with the hearing. I don't understand what you mean by sensitive. If you mean that the drum-membrane is more liable to be ruptured in a patient who has chronic catarrh, and there are changes in the drum-membrane, I say yes. The ear is not necessarily more liable to become inflamed. There is a very great difference between an inflammation of the drum-head and a rupture of the drum-head. A congestion of the drum-head is what is usually termed a redness; the vessels are more dilated, and the part, by examination, appears red and dry, and afterward may throw out some exudation. A rupture is an opening in the drum-membrane—a hole in the membrane. In certain rare cases I have known of people becoming deaf from a blow on the ear. A little child is not more sensitive than a grown person, and his organs of hearing are not more liable to be affected by inflammation from a blow; they are not so liable to be injured. In a climate like this almost everybody has some slight catarrhal trouble. I know there is a sympathy between the organs of the body through the sympathetic system. An affection of one eye will affect the other in certain diseases. That is not necessarily so with the ear, though there is apt to be in a catarrhal patient more or less sympathy between the ears; in catarrhal diseases there is usually an affection of both ears. A deafness from meningitis very often affects one ear. Meningitis is an inflammation of the membranes of the brain that may affect the nerve of one side and not in any way impair the other.

Q. Suppose you had been told that a little boy about six years old who had previously been free from any impairment of hearing (he may have been scientifically deaf, but not in fact) had received a severe blow on the left ear, and that from that time on, or from within two months after that on, his hearing in that ear had been impaired, would you ascribe that impairment of hearing to the blow?

A. I should not. The blow might affect his hearing, but I couldn't say it was necessarily the blow that did it, because I have so many patients come to me complaining of deafness from such a cause, and I find catarrhal difficulty in both ears.

Q. A person suffering from catarrhal difficulty can be more readily made deaf by a blow or shock?

A. If it affects the nerve or ruptures the drum-head.

Q. How if it inflames the drum-head?

A. There is no such thing as inflammation of the drum-head alone. A rupture of the drum-head may be followed by inflammation immediately. Inflammation of the drum-head is not generally classified separately now. There is such a thing as the drum-head being inflamed. It can result from a blow, or from what is called salt rheum or eczema of the external auditory canal, or from an abscess in the external part of the ear extending down to the drum-membrane.

Q. What would create such an abscess?

A. Some constitutional tendency to the formation of pus. It is possible for inflammation of the drum-head to be caused by a blow, but an inflammation of that kind does not in any way affect the hearing in the other ear unless it produces con-

cussion of the nerve of the opposite ear, which it does not do as a usual rule. As a rule, it does not affect the other ear at all. The blow does not affect the catarrh, although a person suffering from chronic catarrh in the head is more liable to deafness from a blow under certain conditions. In this case the blow might possibly have affected the hearing in both ears if it had produced concussion of the nerve. I couldn't tell whether it had produced concussion of the nerve at the time of the blow, if he had recovered from that. I could only say that the nerve was all right in both ears at the time that I examined them. Nobody could tell whether he had suffered from concussion of the nerve at the time of the accident unless he had examined him then.

Q. So that after the lapse of two years you couldn't really tell what had affected the boy's hearing?

A. You couldn't absolutely tell.

By the Court.—Q. Would there or would there not be an indication of a concussion of the nerve so late as when you made this examination?

A. I tested with the tuning-fork and found that at the time of the examination there was no trouble with the nerve. He might have had concussion of the nerve at the time, but it might have been entirely recovered from. There was no evidence that there had been any concussion of the nerve on either side at the time I examined him. If there had been any concussion of the nerve, it could not have caused the deafness that existed at the time I examined him. I could tell absolutely that the trouble was in the middle ear at the time of the examination. I couldn't tell whether there had been an inflammation of the drum-head at the time of the accident. I found inflammation in both drum-heads. He had a fresh attack of catarrh. I found more inflammation in the right ear. He heard better in the right ear, although there was more inflammation in the drum-head, shown from the discharge in the right ear. He heard better on the side where there was the most inflammation. Inflammation of the drum-head does to a certain extent cause deafness in certain cases, but it does not make people absolutely deaf. A chronic catarrhal inflammation of the nasal organs is apt to interfere with the hearing materially; it generally does; it is very apt to extend up the tubes to the ears. Some patients are absolutely deaf from catarrhal deafness, from catarrh of the nasal organs, when it extends up the Eustachian tubes. If it does not extend up the Eustachian tubes to the ear, it does not affect it. I have never heard of catarrhal affection of the nasal organs alone making a man deaf. People are deaf who do not suffer from any catarrhal affection of the nasal organs. I placed the tuning-fork in this case back of the ear and on top of the head. The patient very often does not hare it at all when placed on top of the head if the hearing is normal. It does not follow if he does not hear it that he is deaf, but it is an indication of deafness, and shows that either he has some trouble of the internal ear, or else that his hearing is perfect.

Q. If he does hear it, it shows his hearing is imperfect?

A. It does not. It shows the nerve is affected if he does not hear it, or else it is a normal ear. A patient with normal hearing hears the tuning-fork, if placed alongside of the ear, quite plainly in either ear; if it is then placed on top of the head, he may hear it very slightly or not at all. If you place a tuning-fork on a man's head and he does not hear it, it is an indication either that his hearing is good or else that both nerves are affected.

Q. If he does hear it, is that an indication that his hearing is bad?

A. Not necessarily—under certain conditions. If a patient complains of deafness, and the auditory nerve is not affected, he will hear the tuning-fork much better, if placed on the top of the head, in the affected ear, while, if the nerve is affected, he will not hear it on that side by bony conduction. In this case, when I placed the tuning-fork on the top of the head and behind the ear, he heard it much louder in both ears than when I held it at a distance from each ear. He said he heard it when I placed the tuning-fork on the head and on the bone behind each ear. I then held the tuning-fork about three inches in front of each ear, and he said that he heard it not at all or very faintly. This experiment with the tuning-fork indicates whether there is any trouble of the internal ear or of the middle ear if the patient complains of deafness.* The boy was not in bed at the time. I was told that he had been. I found the hearing worse in the left ear than in the right. All I know is from what the boy answered and the expression of the patient's countenance, as they generally express some pleasure when they hear the sound. I noticed each time from the expression that he heard it. I have heard of catarrh becoming chronic in six months. From the condition of the passages of the nose, the back part of the throat, and the upper part of the pharynx, where the Eustachian tubes enter, I am able to say, in this case with accuracy, that the naso-pharyngeal catarrh had existed more than six months. I found much more thickening, much more obstruction of the nasal passages, than there would have been in six months. I discovered that by getting him to breathe and inspecting the parts with a speculum. I am positive that it had existed more than six months. I don't remember whether Mr. Y. told me, but I was told that the patient had had frequent colds in the head. It was either Mr. or Mrs. Y.; they were both in the room; and they told me that, when he had cold in the head, his hearing was apt to be affected. They told me that condition existed only since the accident. I concluded that it had existed before the accident. I could say that it had existed two years—from the condition of the nasal passages and of the throat—and probably three or four years. Everybody that bathes does not become deaf, though it is very frequent in summer for people who bathe to become deaf. Most of the acute cases that come to the hospital in summer are from sea-bathing, either ruptured drum-head, from the force of the waves in surf-bathing, or inflammation of the drum-membrane or middle ear. It is not necessarily from a single shock, though it does result from a blow of the wave on that side of the ear. It will develop immediately if it ruptures the drum-head, but the presence of the water itself in the ear may set up a gradual inflammation, or it may result from particles of sand in the ear, or things that are apt to be in the water in surf-bathing. The chronic thickening of the nasal passages in this case, and of the back part of the throat or naso-pharynx, where the Eustachian tubes enter, indicated that this was not a sudden cold. There was a good deal of what is called connective tissue thrown out, or thickening of the parts there, and the nasal passages were very much congested, so that he could only breathe with extreme difficulty. I had no means of determining how long this condition had existed but my experience in similar cases of catarrh. You do not have such changes, such thickening and narrowing of the nasal passages, and thickening of the naso-pharynx, in a boy of that age, in six months. I should say that had existed

* From the stenographer's notes the testimony in regard to the use of the tuning-fork is not very plain. What I intended to say was that, in some patients with normal hearing power, when a tuning-fork in vibration is placed on the head, it is not heard at all or very slightly. If, however, the patient suffers from deafness in both ears, and the tuning-fork is heard not at all or very slightly by bony conduction, while by aërial conduction it is heard fairly well, it is probable that the internal ears are affected.—G. B.

at least three or four years. I examined the boy about two weeks ago. Of course I could only tell what I found at that time.

(*To be concluded.*)

Book Notices.

A Reference Handbook of the Medical Sciences, embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Illustrated by Chromo-lithographs and Fine Wood Engravings. Edited by ALBERT H. BUCK, M. D., New York City. Volume I. New York: William Wood & Co., 1885. Pp. vi–808.

WHEN it became known that Dr. Buck had undertaken the preparation of this cyclopædia, it was generally expected that the work would prove to have been exceedingly well done. This expectation will not be disappointed; the volume before us is quite worthy to be ranked with those issued in French by Jaccoud and Raige-Delorme and Dechambre, and with Eulenburg's "Real-Encyclopädie." The pages are very large, double-columned, and closely printed. The subjects are treated of in alphabetical order, and the volume closes with the article on "Cataract." The work is freely illustrated, and most of the cuts are very good. We must say, however, that we attach but little value to the colored plates, four in number; except the second one, showing the spectrum of blood, none of them, we think, give a very accurate idea of what they are intended to represent.

Within the space at our command, a detailed criticism of the work is out of the question. We can only say that the writers seem to have been judiciously selected, and their articles carefully prepared. Besides the choice of authors, the difficult problem has had to be solved by Dr. Buck of how much space should be allotted to the various subjects; and in this matter, it seems to us, he has shown rare discretion. The work is unquestionably one of the most important that have ever been published in this country, and it constitutes a storehouse of information that no one interested in medicine can well afford to do without.

The contributors to Volume I are the following: Willis J. Abbot, LL. B., of Chicago; Gorham Bacon, M. D., of New York; Frank Baker, M. D., of Washington; Elias H. Bartley, M. D., of Brooklyn; E. A. Birge, Ph. D., of Madison, Wis.; Albert N. Blodgett, M. D., of Boston; W. P. Bolles, M. D., of Boston; L. Bremer, M. D., of St. Louis; William N. Bullard, M. D., of Boston; Frank Buller, M. D., of Montreal; Charles H. Burnett, M. D., of Philadelphia; Arthur T. Cabot, M. D., of Boston; Donald M. Cammann, M. D., of New York; Russell H. Chittenden, Ph. D., of New Haven; W. J. Conklin, M. D., of Dayton, O.; William T. Councilman, M. D., of Baltimore; Edward Curtis, M. D., of New York; Charles L. Dana, M. D., of New York; N. P. Dandridge, M. D., of Cincinnati; D. Bryson Delavan, M. D., of New York; Hasket Derby, M. D., of Boston; Henry Fleischner, M. D., of New Haven; William H. Flint, M. D., of New York; Eugene Foster, M. D., of Augusta, Ga.; Frank P. Foster, M. D., of New York; George B. Fowler, M. D., of New York; James M. French, M. D., of Cincinnati; William W. Gannett, M. D., of Boston; William Gardner, M. D., of Montreal; George W. Gay, M. D., of Boston; H. Gradle, M. D., of Chicago; John Green, M. D., of St. Louis; Charles E. Hackley, M. D., of New York; Allan McLane Hamilton, M. D., of New York; Charles Harrington, M. D., of Boston; Frederick P. Henry, M. D., of Philadelphia; William B. Hills, M. D., of Boston; Charles B. Kelsey, M. D., of New York; William G. Le Boutillier, M. D., of New York; Henry Leffmann, M. D., of Philadelphia; George W. Leonard, M. D., of New York: R. L. Macdonnell, M. D., of Montreal; Lewis L. McArthur, M. D., of Chicago; Walter Mendelson, M. D., of New York; T. Wesley Mills, M. D., of Montreal; James L. Minor, M. D., of New York; Charles Sedgwick Minot, M. D., of Boston; William Oliver Moore, M. D., of New York; William H. Murray, M. D., of New York; John H. Musser, M. D., of Philadelphia; William Oldright, M. D., of Toronto; Henry F. Osborn, Sc. D., of Princeton, N. J.; Roswell Park, M. D., of Buffalo; T. Mitchell Prudden, M. D., of New York; Mary Putnam Jacobi, M. D., of New York; Leopold Putzel, M. D., of New York; Joseph Ransohoff, M. D., of Cincinnati; J. C. Reeve, M. D., of Dayton, O.; Huntington Richards, M. D., of New York; M. H. Richardson, M. D., of Boston; Henry A. Riley, of New York; George Ross, M. D., of Montreal; Irving C. Rosse, M. D., of Washington; T. E. Satterthwaite, M. D., of New York; William T. Sedgwick, Ph. D., of Boston; N. Senn, M. D., of Milwaukee; Samuel Sexton, M. D., of New York; Francis J. Shepherd, M. D., of Montreal; Charles Smart, M. D., of the army; M. Allen Starr, M. D., of New York; Thomas L. Stedman, M. D., of New York; Henry W. Stelwagon, M. D., of Philadelphia; George M. Sternberg, M. D., of the army; James Stewart, M. D., of Montreal; Lewis A. Stimson, M. D., of New York; Samuel Theobald, M. D., of Baltimore; William G. Thompson, M. D., of New York; William H. Thomson, M. D., of New York; L. McLane Tiffany, M. D., of Baltimore; Arthur Van Harlingen, M. D., of Philadelphia; William L. Wardwell, M. D., of New York; Charles Ware, M. D., of New York; J. Collins Warren, M. D., of Boston; Leonard Weber, M. D., of New York; Edmund C. Wendt, M. D., of New York; Moses C. White, M. D., of New Haven; George Wilkins, M. D., of Montreal; Charles F. Withington, M. D., of Boston; John McG. Woodbury, M. D., of New York; and W. Gill Wylie, M. D., of New York.

BOOKS AND PAMPHLETS RECEIVED.

Lectures on the Diseases of the Nose and Throat, delivered during the Spring Session of Jefferson Medical College. By Charles E. Sajous, M. D., Lecturer on Rhinology and Laryngology in the Spring Course of Jefferson Medical College, etc. Illustrated with One Hundred Chromo-lithographs, from Oil-paintings by the Author, and Ninety-three Engravings on Wood. Philadelphia: F. A. Davis, Atty., 1885. Pp. xii-439.

The Blot upon the Brain: Studies in History and Psychology. By William W. Ireland, M. D., Edin., formerly of H. M. Indian Army, etc. New York: G. P. Putnam's Sons, 1886. Pp. viii–374. [Price, $3.]

LETTER FROM LONDON.

General Parliamentary Election.—Medical Candidates.—The Royal College of Surgeons and its would-be Reformers.—The Want of a Degree for London Students.—The Recent Addresses of Dr. Wilks and Dr. Hughlings Jackson.

London, *November 23, 1885.*

Our parliamentary elections take place this week, and the final result of them will be known to you before this letter is in type. The chief interest of the present general election to a medical writer lies in the possibility, and I hope I may say probability, that the new House of Commons will include a larger proportion of medical members than it has ever done before. The chamber which has just been dissolved contained only four doctors; that number, we hope, will be at least doubled in the new House. Some members of the profession are putting up for election, who, if successful, would be a real gain to Parliament. Mr. Erichsen, the well-known surgeon and surgical author, is standing in the Liberal interest, with a good prospect of success, for the Universities of Edinburgh and St. Andrews. Mr. Ernest Hart, the clever editor of the "British Medical Journal," is standing for a division in the East End of London. Sir Guyer Hunter, a retired Indian surgeon and professor of medicine at Bombay, who got his knighthood for services in connection with the outbreak of cholera in Egypt in 1853, also stands for an East End division, but in the Conservative interest, and therefore I fear with small prospect of success. Dr. Alfred Carpenter, the well-known authority on sewage-disposal, is putting up for a rural district, and other unknown medical men are courting the electors in other parts of the country. The seats of at least two of the doctors who sat in the last Parliament are safe, so that we shall all be very much disappointed if the new House of Commons does not contain a strong enough band of medical and sanitary authorities to prevent important measures of public health from being strangled by the press of other business, or shuffled into law without sufficient discussion.

It is not possible for any one on this side the water, who has not carefully studied your medical journals, to understand the exact merits of the unfortunate dissensions which are tearing your body asunder, but I am sure that the sympathies of all, except a few whose vanity is upset by the slightest waving of the red rag of ethics, are with the known and honored men who have withdrawn from the Congress organization. Rightly or wrongly, we, who have been brought up in an old and well-disciplined community, are influenced more by names than by numbers, and I fancy that most of us would rather take the chance of erring in company with Bowditch, Weir Mitchell, and Bartholow than make common cause with a legion of unknown practitioners. On one point, I believe, we should all be found unanimous, and that is that it is in the highest degree unadvisable that an international Congress should be "run" by any medico-political association of the host country, however powerful. Our British Medical Association is, as you know, as large and as influential as any medical society in the world, but no one in this country would think for a moment of allowing it to interfere in the organization of an international Congress. Successful as it is, the association is overshadowed and its influence balanced by bodies which came into the field before it, and which include the *élite* of the profession, both as regards character and ability. The Royal College of Physicians and the Royal College of Surgeons are universally admitted to represent the highest medical knowledge and the strictest medical honor, in spite of oligarchical constitutions which you would not tolerate for an instant. The popular cry here now is for their reform, but there is a very strong feeling against converting them into bodies like the British Medical Association, in which numbers shall swamp tried judgment and ability. The College of Surgeons is at present under attack. The college, as you may know, has the best medical licensing business of any corporation in the three kingdoms. It examines many hundred candidates *per annum*, and last year it received over twenty thousand pounds in examination fees. About half this sum is enough to provide for the expenses of the examinations; the rest goes to maintain the magnificent museum and library, and meet other working expenses of the college. By far the greater part of the college in-

come is derived from the fees paid by the members, of whom there are nearly 17,000. The higher grade—the Fellows—who have to undergo much stiffer examinations than the members, number less than 1,200. And yet the right of choosing the governing body of the college is restricted to these 1,200 Fellows, while the 17,000 members, from whom the college has derived the main part of its princely income, have no voice whatever in its administration. The injustice and unwisdom of this arrangement have long been felt, and at length an association has been formed with a view to inducing or constraining the Council of the college to allow the members to vote for, and, if chosen, to sit upon, the governing body. One additional privilege has already been conceded to the members by the Council, viz., that of meeting once a year in the college theatre to receive and discuss a report from the Council, though no right of rejecting or amending the report is allowed. On October 29th this meeting took place, and a strange scene it was. The large theatre of the college was crowded by Fellows and by members who had been whipped up by the association. Tier above tier of the amphitheatre, and all the seats in the galleries above, were filled with men, each of whom had paid some £20 for the college diploma, but who were now little more than strangers within its gates. In the central well the members of the Council sat, sphinx-like in their silence, while the pent-up indignation of years burst forth from speaker after speaker, many of whom had come from distant towns to join in the demonstration. It was a painful scene, for the Council is composed of the most respected men in the profession; but they have been caught in the toils of a bad system, and have to suffer for the sins of their predecessors, of which, you may be sure, angry speakers did not omit to remind them. Many of the Council are men of most liberal minds, and in all other respects eager for advance (I need only mention the names of Mr. Savory, the president; Sir James Paget, Sir Spencer Wells, Sir Joseph Lister, Mr. Jonathan Hutchinson, and Sir W. MacCormac, to prove this); but as soon as they take their seats on the College Council they seem to say good-by to their liberalism, and to identify themselves with the narrow traditions which the college has derived from the time when it was a simple city company. At the meeting in question they all sat impassive and silent, as though by previous arrangement, and allowed their system to be arraigned and motions to be passed over their heads without a single word of explanation or defense. A resolution was passed, by something like three hundred votes against eight, that it was desirable that the members should be allowed to take part in the meeting of the Council, but the great men said never a word. They had their revenge, however, for, on November 14th, they met together and decided unanimously that the demands of the members should not be granted. The reason for this decision will be made known at another meeting of Fellows and members, to be held on December 17th. The members are, of course, disheartened by their defeat; but, if they will press on, victory is assured them sooner or later. I am afraid I shall weary your readers with this long account of what may appear to them a tempest in a teapot. But the Royal College of Surgeons is really our most important medical body, and is destined, through the munificent bequest of the late Sir Erasmus Wilson, to take a still more prominent part in the advancement of medical science than it has hitherto done. It bids fair to become the center of pathological research in this country, and to be a really worthy monument of John Hunter. In conjunction with the Royal College of Physicians, it proposes to seek university rank and the degree-giving power, so that the licentiates of the two bodies shall be able to write the coveted M. D. after their names instead of the cumbrous L. R. C. P., M. R. C. S. And, probably, in the not very distant future, it may actually combine with the College of Physicians to form one Royal College of Medicine, which would then be far and away the most important and influential medical body in the empire. Under these circumstances, I think it will be admitted that it is highly important that the administration of the college should be conducted on a large and liberal basis, and that it should be able to make sure of the loyalty and to dispose of the administrative ability of all its licentiates, instead of remaining, as it is now, a practically close corporation, under the irresponsible government of a handful of hospital surgeons.

The entries of new students at the London hospitals this year do not show any marked increase on the comparatively low figures of previous years. It is disappointing, as year after year goes by, to find the prosperity of London as a center of medical education still under a cloud; and every one is now beginning to see that, unless London students are afforded the same opportunities of acquiring a medical degree that the students of other schools have, there is no prospect of any great increase in their numbers. London, with its many splendid hospitals, its immense mass of clinical material, and its eminent clinical teachers, ought to be able to take the place of a "finishing-school" for students from all parts of the country, and even from the colonies and from the United States. As it is, we find even our own students running away from London by the score, just at the period of their curriculum when they are in a position to make good use of its wealth of clinical material and talent, in order to spend a year or two at some northern university which will give them a degree. At the same time the medical students at the Scotch universities and the English provincial schools are steadily increasing in numbers, while the number of London students remains practically stationary. A cry has thus arisen for a medical degree for London students, and, somehow or other, we shall obtain it. The University of London examinations are so severe that only a small percentage of students can take that degree. Fifty-one have obtained the M. B. degree this year, out of an average annual entry of six hundred. It is for the other five hundred and more, or for the greater part of them, that a degree is wanted, and there are several proposals on foot for dealing with this want, of which I hope to say something in a future letter.

Important lectures have just been given by two London physicians well known for their contributions to neurological medicine, and they are both worth careful reading. The one was addressed to the Midland Medical Society by Dr. Wilks, one of our leading pathologists and most philosophical physicians, whom another year or two may very probably see in our chief seat of honor, the presidency of the College of Physicians, in succession to Sir W. Jenner. Dr. Wilks's address mainly dealt with the proper place for drugs in the treatment of disease. It will not, possibly, commend itself to the enthusiastic pharmacologist who still cherishes the hope to find a specific to cure every disease, and a drug to touch every symptom, but it will, I think, be read with pleasure and assent by every observant and thoughtful practitioner. The other address—the Bowman lecture, by Dr. Hughlings Jackson—is more "caviare to the general," and requires a previous study of Herbert Spencer to render it plainly intelligible. Dr. Jackson is a profound student both of philosophy and of disease. His disquisitions are spoken of with bated breath by the most distinguished of his colleagues, who are not ashamed to confess that he often takes them beyond their depth. His accepted *métier* is to bring morbid phenomena within the scope of the Spencerian philosophy, to act in some sort as the medical exponent of Herbert Spencer; but, with all regard for Dr. Jackson, it seems as though he would have to find an exponent himself before his profound thoughts are brought within the reach of the average medical intellect.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, DECEMBER 12, 1885.

A NOTABLE DEPARTURE FOR PARIS.

Last Wednesday may perhaps become as prominent in the chronology of preventive medicine as it certainly will in that of philanthropy, for on that day a ship left this port having on board four little children who within a week had been bitten by a mad dog, and, by the generosity of a few citizens, were enabled to start upon a voyage of which the purpose was to bring them into the presence of M. Pasteur, who had kindly undertaken to do his best to rescue them from a horrible death.

In brief, the circumstances are these: One day last week six children, living in Newark, New Jersey, were bitten by a dog that was supposed to be rabid. As usual, unfortunately, the dog was killed, but this disturbing element is in great part compensated for by the fact that so capable a veterinarian as Mr. Billings, of the New York Polyclinic, has declared his conviction that the animal was really suffering with rabies. As good luck would have it, the children fell into the hands of a physician who evidently keeps himself informed of what is going on in the world, and is not so consumed with doubt as to fight against what may prove to be a good thing, simply because it has not yet been irrefragably proved to be one—Dr. O'Gorman, of Newark. The doctor at once made up his mind that the children ought to be sent to Pasteur, and he backed up this sensible conclusion by contributing liberally toward the necessary expenses of the trip, and by inciting others to do likewise. The result has been, not only that an abundance of money was promptly forthcoming, but even that there has been such emulation in the work that one gentleman's offer to defray the whole expense has had to be declined.

Not the least satisfactory feature of the affair is the fact that the children are accompanied by Mr. Billings, who will look out for them on the trip, and will constitute one of the very best observers of M. Pasteur's system of inoculation that this country could have sent. It is not unlikely, too, that a representative of the Carnegie Laboratory, Dr. Biggs, will be enabled to witness the treatment, for we understand that he also has sailed for Europe, presumably with that object in view. Indeed, that institution, backed by its founder, is said to have stood ready to undertake the whole cost and responsibility of the pilgrimage; only, as we have said, this had been rendered unnecessary by the prompt subscription of the funds needed and by Mr. Billings's readiness to go. There is one drawback to what we all hope may be the glad outcome of the voyage, and that is that two of the children have been left behind, their parents having refused to allow them to depart. Another fact that is perhaps calculated to dampen our ardor is the report of the death of one of the persons on whom M. Pasteur's system has been tried. This, however, may be susceptible of a satisfactory explanation; at all events, we may be sure that it will not be glossed over, for never did a man in Pasteur's position show more candor or a greater desire not to carry assertion beyond the warrant of facts. For our part, we are still hopeful that his plan of protective inoculation will be demonstrated to be successful.

Persons who have been bitten by mad dogs are reported to be flocking to Paris, even from such distant countries as Algeria, but a pilgrimage across the Atlantic for that purpose must still be considered a most notable event. If Pasteur's treatment stands the test, familiarity with its technical details can not long, in the interest of humanity, be confined to Paris or to any great center, for it is not to be supposed that circumstances always and everywhere will be such as to enable victims to be sent there without dangerous delay; but for the present this ought by all means to be done whenever it is possible.

THE ARMY MEDICAL SERVICE.

The annual report of the Surgeon-General of the army, recently issued, although not bulky, being but a pamphlet of not quite a hundred pages, is sufficiently full to contain valuable data and to prove interesting reading. The first part of the report is devoted to a synopsis of the condition of the force from the point of view of health. It seems that, as during the preceding year, the cavalry has suffered disproportionately from typhoid fever. The rate for venereal diseases in general remains the same as it was the year before, but that for syphilis is two per cent. lower. Respiratory diseases were the most prevalent of all; diarrhœa and dysentery were also prominent. Of the infectious diseases, there were sixty-eight cases of mumps, sixty-one of measles, two of varioloid, sixty-one of erysipelas, one of chicken-pox, and eight of diphtheria. The percentage of mortality among native-born white troops was 6·6, among foreign-born white troops 12·9, and among colored troops 14·1, thus, as the Surgeon-General remarks, bearing out the popular belief that the native white American has a greater proportion of vital force, and greater resisting power to disease and death, than foreigners and negroes.

A table is given of the surgical operations performed during the year, and histories of a few individual cases have been appended to the report. Sections are devoted to the work of the Record and Pension Division, to the Medical Museum and Library, and to various other matters of interest to the profession. It is stated that the manuscript of the third volume of the "Medical and Surgical History of the War of the Rebellion," which is to be the last of the series, is now well advanced toward completion, and that it will probably be ready for issue before the close of the winter. Much interesting statistical matter, illustrated with graphic representations, is given at the close of the report. We must congratulate Surgeon-General Murray on the excellent condition of his corps, as shown in the report.

MINOR PARAGRAPHS.

THE MANAGEMENT OF STRAY DOGS.

The "Lancet" commends a London institution known as the Temporary Home for Lost and Starving Dogs. Owing to the present prevalence of hydrophobia in London, there has lately been a great increase in the number of stray dogs cared for by the institution, for they are brought to its doors by the police. As many as nine hundred were received in the course of six days. Our contemporary points out a conspicuous service to humanity rendered by the home, in addition to the benefit to the dogs—that, namely, of keeping sick animals under watch until it can be determined positively whether they are or are not affected with rabies. If London, in the face of almost an epidemic of hydrophobia, can afford to be so humane to vagrant dogs, what excuse is there for our annual period of legalized brigandage, when the chief occupation of a set of miserable ants termed dog-catchers is to steal or forcibly capture animals that are in no sense vagrant, merely that they may exact ransoms?

THE DISINFECTION OF RAGS.

Up to the time of going to press we have not heard of any special effort having been made to secure the approval of the American Public Health Association, which began its meeting in Washington last Tuesday, for the process which, as one of the daily papers puts it, oppresses the importers at this port. The paper in question has thought it best to warn the meeting against the blandishments of persons who are openly or secretly interested in the company that works the process, and were likely to attend the meeting. The hint was certainly not uncalled for, and we hope that nothing will come to light to show that it has been unavailing.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 8, 1885:

DISEASES.	Week ending Dec. 1.		Week ending Dec. 8.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	0	0	0
Typhoid fever	22	8	18	5
Scarlet fever	33	5	25	8
Cerebro-spinal meningitis	3	3	4	4
Measles	8	1	10	1
Diphtheria	75	29	92	45
Small-pox	3	2	12	1
Yellow Fever	1	1	0	0

The Carnegie Laboratory.—Dr. Herman M. Biggs, instructor in the Carnegie Laboratory, sailed for Europe in the Ems last Wednesday. The object of his mission is to visit the laboratory of Pasteur and learn all that he can from him in reference to the preparation of the virus for the inoculation against hydrophobia. He will then visit Koch's laboratory in Berlin, and obtain from him his views upon this subject of inoculation. He will then go to Cambridge, and pay his respects to John Burdon Sanderson, whose work in this department has a world-wide reputation. After a visit to Edinburgh, Glasgow, and London, he will return in two months to institute some elaborate experiments on a large scale. A small farm will be provided in connection with the Carnegie Laboratory where a system of inoculations can be perfected and some observations made in reference to diseases due to a special microbe.

Mr. Carnegie has just presented the Bellevue Hospital Medical College with six thousand dollars for the purchase of more scientific apparatus in addition to the five thousand dollars for this purpose which he gave last year. He has further signified his willingness to contribute annually for the support of this institution and for the purpose of encouraging scientific work. Dr. Biggs has gone to Europe independent of the Newark children, and his entire expenses have been defrayed by Mr. Carnegie. It is a matter of no small importance that an institution can send to Europe a scientific man for any special observation, and this fact with many others betokens a great future for American medicine and surgery. There are now three paid assistants in the Carnegie Laboratory, and one hundred and forty students and practitioners daily at work in the building, and great results are to be expected from an institution which is carried on upon such a liberal basis.

Within the next six months four original papers will appear which will represent original work done in the Carnegie Laboratory.

The Boston Water-Supply.—It is said that an idea originated by Dr. Thomas L. Jenks, a member of the Massachusetts Medical Society, has lately been brought to the attention of Mayor O'Brien and the Water Board, by which, it is thought, a great improvement can be brought about in the quality of the water. The plan is to build an open conduit, a mile or more in length, from the outlet of the system, in which large, rough bowlders are to be placed. The water, rushing swiftly over and between these rocks, will be so agitated, it is presumed, as to do away with that impurity which depends upon partial stagnation.

The Harvard Medical School.—We learn that Dr. John P. Reynolds, who for ten years has been professor of obstetrics, has resigned the chair. He succeeded the late Dr. Buckingham, having previously been an instructor. We understand that Dr. Reynolds's resignation is a matter of general surprise, coming as it does so soon after the opening of the term, and that his successor can not be appointed in less than a month. Meantime President Eliot has asked Dr. William L. Richardson to perform the duties of the position, and it is thought that he will undoubtedly succeed to the chair. Dr. Richardson has been connected with the department for a number of years, and it has been owing largely to his work that the instruction in obstetrics at Harvard has been so satisfactory. Dr. C. M. Green assumes the duties that have heretofore fallen upon Dr. Richardson.

Information concerning a Thief has been given to the police by a Madison Avenue physician, the offender being a young man of good appearance, stout of build, about five feet eight inches tall, with a smooth red face, who summons physicians to call on imaginary patients, and robs their premises while they are away.

The Illinois State Board of Health and the Regulation of Medical Practice.—A decision is reported to have been made recently by one of the Illinois courts which, it is thought, will have the effect of greatly abridging the board's power in the administration of the Medical Practice Act. It seems that a graduate of the Rush Medical College, of Chicago, was licensed by the board in 1877, but that the board subsequently revoked the license for an alleged violation of the law. A suit brought by the practitioner has resulted in a decision which practically limits the board's power to that of the verification of diplomas and the identification of their holders, without power to revoke any license it may issue. If this decision is final, it can not but be looked upon as a severe blow to the spirit of the law, however it may accord with its letter, and is on all accounts very much to be regretted.

The Law concerning Medical Testimony, which prohibits physicians from divulging their patients' secrets on the witness-stand, when they have been communicated to them as information necessary to an understanding of the case, was lately put forward by an Oswego practitioner as a reason for his refusing to give certain testimony in an action for assault. He was fined for contempt, and committed on his refusal to pay the fine. It is thought that an appeal will be taken.

Society Meetings for the Coming Week:

Monday, *December 14th:* New York Ophthalmological Society (private); New York Academy of Medicine (Section in Surgery); New York Medico-Historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

Tuesday, *December 15th:* New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings; Ogdensburg, N. Y., Medical Association.

Wednesday, *December 16th:* Northwestern Medical and Surgical Society of New York (private); Medical Societies of the Counties of Allegany (quarterly) and Tompkins (semi-annual—Ithaca), N. Y.; New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society (Clinico-Pathological); Stafford, N. H., District Medical Society (annual—Dover).

Thursday, *December 17th:* New York Academy of Medicine; New Bedford, Mass., Society for Medical Improvement (private); Medical Society of Addison County, Vt. (annual).

Friday, *December 18th:* Chicago Gynæcological Society.

Saturday, *December 19th:* Clinical Society of the New York Post-Graduate Medical School and Hospital; Roman Medical Society (private).

Letters to the Editor.

PAYING ONE OF OUR 'PENALTIES FOR THE LOW STANDARD OF MEDICAL EDUCATION IN AMERICA.

To the Editor of the New York Medical Journal:

Sir: Now that the failure to hold the Ninth International Medical Congress in America is passing into history as a fact, one is rather disposed to look over the field with the view of discovering, if possible, some hidden cause for this lack of success. Something behind personal ambition; something behind the untimely action of the American Medical Association; something behind the code controversy. We must believe that these can be nothing more than the prominent symptoms of some deeper-seated disease, that has led to the fatal issue. If any or all of them had been successfully treated, would it have made an iota's difference with the final result? Would not the cancer still have had its own way, and death been unavoidable?

We see representatives of other departments of science hold their congresses, while their members flock from all parts of the world, to invariably convene their councils in harmony, and transact their affairs with success. Hardly a year passes without some such meeting, whether it be of geologists, astronomers, naturalists, or ornithologists, yet in these days we never hear of any serious jars at their gatherings, and I can attest to the fact that it is not for the lack of disputed questions. It certainly seems strange, then, that such a disaster as has befallen the efforts of the representatives of American medicine this year should lie within the range of possibilities. A profession, too, that has so noble a goal for its object, and one upon which humanity has so many claims. Can it be that the disciples of Darwin, of Herschel, or of Linnæus have a greater love for their work, seek more closely after the truth, and more rarely look for pecuniary gain in their pursuits than do the advocates of physic? These facts may all have more or less to do with it, but the root of the matter is still deeper, for I believe it involves the question of education. I mean by this that we are now reaping in this disgraceful contention some of our deserts for the way in which medicine has been permitted to grow up in this country. Our dishonor is due to our second- and third-rate medical colleges, which have been allowed to flourish, and turn loose upon us for years hosts of semi-educated men, who hold a vote for weal or woe in the profession quite as potent as the one cast by a Gross or a Sims.

This becomes the more evident when we regard in an unprejudiced light the issue as it now stands. With at least one notable exception—and every rule, it is said, must have its exception—we find one, and by far the smaller, faction represented entirely by men who have, through their works and influence, made American medicine what it is; while, on the other hand, we see arrayed against them another faction, which includes medical men of the association totally unknown to the profession at large—the aforesaid exception—and an enormous constituency, largely the outcome of the class of colleges alluded to above.

It has been the clamorous charge of this latter element for a representation in the Congress, and the American Medical Association, or rather the unprincipled part of it, have been their mouth-piece, which has succeeded in routing the movers and defeating the efforts of the original committee.

A great deal might be said touching this point, as we come to examine into it more closely, which lack of space forbids entering upon, though, as we ponder upon it, its truth, I think, will become more and more clearly revealed to us as time rolls by.

R. W. Shufeldt.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of December 3, 1885.

The President, Dr. A. Jacobi, in the Chair.

Nominations were made as follows: For Vice-President, Dr. H. D. Noyes and Dr. William H. Draper. For Recording Secretary, Dr. A. M. Jacobus, Dr. George L. Peabody, and Dr. Frank P. Foster; Dr. Katzenbach declined to be renominated. For Corresponding Secretary, Dr. H. J. Garrigues, Dr. A. R. Robinson, and Dr. Wesley M. Carpenter. For Treasurer, Dr. W. F. Cushman, Dr. J. D. Bryant, and Dr. D. B. St. John Roosa. For Committee on Admissions, Dr. J. H. Emerson and Dr. Laurence Johnson. For Committee on Ethics, Dr. S. O. Van der Poel and Dr. Joseph D. Bryant. For Committee on Education, Dr. D. B. St. John Roosa, Dr. David Webster, and Dr. Charles Heitzman. For Committee on the Library, Dr. W. H. Katzenbach for the full term, Dr. J. H. Andrews for the short term, Dr. Laurence Johnson, Dr. R. W. Amidon, and Dr. C. T. Poore. For Trustee, Dr. S. T. Hubbard was renominated, but declined; Dr. George A. Peters and Dr. James H. Anderson were nominated. For Delegates to the State Medical Society, to serve four years, Dr. W. R. Birdsall, Dr. H. J. Boldt, Dr. H. C. Coe, Dr. J. W. Howe, Dr. R. W. Amidon, Dr. Bullard, Dr.

Goodwillie, Dr. E. Herrick, Dr. C. Heitzman, Dr. J. A. Andrews, Dr. A. S. Hunter, Dr. G. Bacon, and Dr. W. L. Hardy.

A Review of the Life of Dr. Louis Elsberg and of the Advancement of our Knowledge of Diseases of the Throat during his Professional Career was then read by Dr. M. H. Henry. [See page 621.]

Original Deductions based on a Study of One Hundred Cases of Fracture of the Upper Extremity, excluding the Hand.—Dr. Samuel W. Smith read a paper with this title. He professed no originality in the general plan of treatment, except in the use of splints which he had invented, and which he believed had never been used before. His constant aim in treatment had been to place the fragments in such a position as would be most likely to result in complete union without deformity, allowing the patient as much ease and comfort as possible. He then presented his tabulated list, and said that nearly half of the fractures had occurred to children under twelve years of age. Of these, twenty-five were of the clavicle, eight of the condyles of the humerus, and one of the lower end of the radius. In patients over twelve years of age, twelve were of the clavicle, three of the condyles of the humerus, and twenty-four of the lower end of the radius. Of the twenty-five fractures of the clavicle in children, twenty-two were transverse with and occurred near the outer edge of the middle third, there being only slight displacement of fragments; in the three others the fracture occurred near the middle of the bone, was oblique, and was accompanied by considerable deformity. Of the eight fractures in persons between twelve and fifty years, three resulted from great violence at the upper and outer portion of the shoulder, the line of fracture commencing near the inner edge of the middle third and running from above downward and inward, causing great displacement of the fragments, the outer fragment being drawn downward and inward. Of the five other cases, in three the fracture was oblique, running from the outer portion of the middle third backward and inward, causing less deformity than in the other three mentioned; in five other cases the fracture was in the outer portion of the middle third.

In speaking of fractures of the humerus, he confined his remarks to fractures of the condyles or separation of the epiphysis. Of eleven fractures of the condyles, two occurred in children under six years of age, one of the external and the other of the internal condyle; six between the ages of six and twelve, including one of the epicondyle, three of the external condyle, one of the internal condyle, and one so-called "T" fracture. Three occurred in persons between twelve and fifty, one being of the epicondyle, one of the external condyle, and one of both condyles.

Regarding fractures of the radius, the author confined his remarks to Colles's fracture, and said he conceived a marked difference between this fracture and a transverse or short oblique fracture. In the latter the characteristic deformity described by Mr. Colles did not exist unless there was also impaction of the upper fragment. The kind of splint used and the after-treatment depended largely upon the obliquity of the fracture; if the obliquity was great, the action of the supinator longus and the extensors constantly drawing the lower fragment upward, its carpal end and the carpal bones backward, and the hand outward, there would be difficulty in retaining the fragments in good position, and there would be danger of posterior deformity and the appearance of dislocation of the ulna.

There were in his list twenty-five fractures of the lower end of the radius; of these, two occurred to children under twelve, one of which was transverse and one a separation of the epiphysis with no deformity. Eleven patients were between the ages of twelve and fifty; of these, eight had short oblique or transverse with some deformity, and three had Colles's fracture, deformity being well marked; twelve fractures occurred to patients over fifty years of age, and of these two were short and oblique or transverse, with considerable of the characteristic deformity of Colles's fracture, but easily reduced and readily held in position. The remaining ten were Colles's fractures, the characteristic deformity being well marked in all of them.

The main object to be attained in the treatment of fracture of the clavicle was to lift the shoulder upward, outward, and backward, and to hold the fragments in apposition. The three methods most commonly in use were Desault's, with the axillary wedge, Dr. Sayre's adhesive-plaster splint, and to some extent Dr. Moore's figure-of-eight splint. Desault's method interfered seriously with the circulation in the arm. Dr. Sayre's method had been inefficient in cases in which the bone was fractured in the great convexity, and the obliquity was downward and inward; it also interfered in these cases with the circulation in the arm. A very great objection was the irritation of the skin produced by the plaster. Dr. Moore's method answered the purpose only where the fracture was near the outer edge of the middle third, and was transverse or short-oblique in character; but where the fracture was near the inner third, and oblique, it did not answer its intended purpose, but did the opposite, for, the end of the shawl, passing backward over the shoulder, pressed the outer fragment downward instead of holding it in apposition with the inner fragment. Nor did it suffice to draw the elbow backward and inward enough to overcome the action of the subclavius muscle, which the author thought was the main factor in drawing the outer fragment inward. This had led him to carry Dr. Moore's idea a step farther by making a clove-hitch with a scarf around the forearm well up to the bend of the elbow, passing the loose ends across the back and over the uninjured shoulder. This enabled him to draw the elbow of the injured side farther backward, inward, and upward, and to make the os brachii a lever and the side of the chest a fulcrum by which he could lift the shoulder of the injured side upward, and throw it outward and backward. It was for this fracture, oblique downward and inward, and through the great convexity of the bone, that he alleged for his new splint for fracture of the clavicle all the advantages of any other, as well as some advantages which no other possessed. The improved splint was described as follows: "It is a padded, gauntlet-shaped piece of leather, laced to fit the forearm, running on either side back of the bend of the elbow. To this part are attached a strap and buckle. A padded collar, with strap, buckle, and ring, is fitted to the uninjured shoulder. Through this ring the strap from the elbow-piece passes, and, by tightly drawing this strap, the arm of the injured shoulder is brought under sufficient control to bring the fragments into perfect apposition. A sling is made to pass from the ring to the collar on the uninjured side of the neck for the hand of the injured side."

Fractures of the condyles of the os brachii extending into the joint were generally caused by direct violence, with much injury to the soft parts; hence it was of special importance in treating them to use means that would most effectually promote absorption of the resulting inflammatory products in and around the joint, as well as the speedy coaptation of the fragments and holding them firmly in position, thus avoiding gun-stock deformity. His experience in treating injuries of the elbow joint, whether with or without fracture, had taught him that prompt and vigorous treatment, to combat local inflammation and effusion into and around the joint, and appropriate treatment for absorption, constituted our only safety against false ankylosis.

A varied experience, full of disappointments, in the use of the known splints for the severer fractures of the condyles had set him to work to make a splint with the following requisites:

1, to hold the fragments in apposition; 2, to lengthen or lessen the external lateral angle of the arm, with fixation; 3, to leave the entire elbow joint exposed for local treatment during the whole time of wearing the splint without disturbing it.

He then described his splint. It consisted of two rods of untempered steel, extending from the upper part of the arm to the wrist, with a ball-and-socket joint at the elbow, and screws for fixation; the lower ends passed into a sheath screw on either side of the wrist. The upper ends passed through two iron posts set in tin and made fast to the arm by plaster-of-Paris bandages, the rods being made firm in the posts by thumb-screws. On each side of the wrist was a post through which the sheath-screw passed, and it was made fast to the wrist in the same manner as the upper parts, and fastened with fixation-screws. By moving the sheath-screws the lateral angle of the arm could be contracted or widened as needed, thus overcoming any tendency to loss of the carrying point, or gun-stock deformity. A turn of the fixation-screws at the elbow and wrist would allow the forearm to be flexed, extended, pronated, supinated, and fixed at any desired point without other interference with the splint.

Regarding the time for passive motion, he thought it depended in each case on the extent of the injury to the soft parts and our ability to hold in check and reduce the inflammation following the injury. Thus, while it might be wisely begun within a week of the injury in one case, in another case it would be better not to begin for three or four weeks.

He would leave the discussion of the application of his splint to Colles's fracture for a future paper. He then cited some cases in illustration of the points made in his paper.

Dr. J. D. Bryant thought the function of the clavicle was essentially to hold the shoulder backward, upward, and outward, and, whenever the bone was broken in a position to allow the fragments to override each other, the shoulder would fall downward and forward. If fracture took place at the anterior border of the deltoid and trapezius muscles on the one hand, and at the sterno-cleido-mastoid and pectoralis major on the other, there would be marked deformity. He could not agree with the author of the paper that the subclavius muscle played an important part in the production of the deformity. As to treatment, any apparatus which secured the fragments in their reduced position would fulfill the indications. He had used Sayre's method by adhesive plaster successfully; Moore's method also fulfilled the indications, and he should judge, from a casual examination, that the apparatus employed by Dr. Smith would likewise fulfill the indications, and if it would it was superior to the others mentioned in being free from certain disadvantages which they possessed.

Dr. A. C. Post thought the most important distinctions with regard to location of fractures of the clavicle were those which occurred at the inner side of the coraco-clavicular ligament, those which occurred between the coronoid and trapezoid ligaments, and those which occurred on the outer side of the trapezoid ligament. In the first situation fracture of the clavicle caused considerable deformity as a rule, the bone being shortened and allowing the shoulder to fall, the outer fragment being below the level of the inner fragment; in the second situation there was little deformity, and little treatment was required except rest and support by a sling; in the third situation there was considerable deformity, but entirely of a different character from that accompanying fracture on the inner side of the coronoid ligament. The shoulder was thrown forward, and the short fragment, connected with the acromion, was placed at nearly a right angle with the long fragment, and was almost on the same level; there was no falling.

Dr. A. H. Goelet had used a bandage similar to that employed by Dr. Smith, but made of roller bandage, in a case of fracture of the clavicle in which the adhesive plaster employed in Sayre's method of treatment had given rise to great discomfort. The change gave the patient complete comfort.

Dr. Smith, in closing the discussion, said he had followed Hamilton's division of the clavicle into thirds. His cases had led him to believe that the subclavius muscle played an important part in the production of the deformity. Only one of his fractures was in the outer third of the clavicle.

Reports of Infectious Diseases.—Dr. C. R. Agnew offered the following resolution:

Resolved, That it is the opinion of the Academy of Medicine that any judicial or other action which in its effect discourages members of the medical profession in making early reports to the Board of Health of cases of supposed contagious or infectious diseases is contrary to public policy and most detrimental to the interests of public health. Carried unanimously.

NEW YORK SURGICAL SOCIETY.

Meeting of November 24, 1885.

The President, Dr. Charles McBurney, in the Chair.

Excision of the Tarsal Bones.—Dr. Charles T. Poore read a paper on this subject. [See p. 652.]

Dr. H. B. Sands said that it seemed to him that a distinction must be drawn between tubercular inflammation and osteomyelitis of the os calcis. So far as he had been able to judge while listening to the paper, Dr. Poore had reported only one case of true necrosis of the bone. In this there was a cavity with healthy walls, inclosing a piece of dead bone, which was removed by operation because the cavity would not close. It was further stated that in this case when the os calcis was removed it was found to be firmer than normal, which would imply that it was not carious, and that the previous failure to obtain a cure was, as Dr. Poore had intimated, due to a refusal on the part of the bony cavity to fill up. The speaker doubted the necessity of removing the whole os calcis in cases of necrosis unless the necrotic process involved the entire bone, the indication being to remove only the loose sequestra. He recalled a case which had occurred about fifteen years before in a lad ten years of age, who was supposed, by the late Dr. Van Buren, the late Dr. Parker, and himself, to be suffering from caries of the tarsus. There were several sinuses in the foot, and it was advised that the foot should be amputated. But an exploratory incision was made, and the os calcis was found to be a shell, containing a large number of pieces of dead bone within a cavity which had a smooth lining, such as was usually found in bones containing necrotic tissue. The pieces of dead bone were removed, and, although the walls of the os calcis were exceedingly thin, the cavity filled up within a few months, and the wound healed. He had not had much experience in dealing with the os calcis in children, but he thought that in adults partial excisions were often successful. He was somewhat surprised to learn that caries was so often limited to the os calcis. His own experience had been that this disease was apt to attack the astragalus and scaphoid, and other bones of the tarsus, rather than the calcaneum alone. He thought the tendency nowadays was to avoid excisions in cases of caries, and that the use of the gouge or sharp spoon, as it was called, often gave satisfactory results. He believed that in one of the children presented the condition of the foot corroborated the statement which he had made a month ago—that after the removal of a large portion of the tarsal bones, provided the periosteum was left, considerable reproduction would occur. It was evident in that case that, although the entire os calcis had been

removed, there had been a considerable reproduction of bone. It seemed to him to be a point worthy of consideration whether, in caries, excision should be preferred to an operation which was partial, and which aimed to remove only the diseased tissues. It might occur, however, that, if a large part of the interior of the os calcis was removed, the space would remain open, although much might be done to overcome that difficulty by nailing down the soft parts or fastening them by deep sutures. He was willing to admit, however, that the results obtained in Dr. Poore's cases had been excellent.

Dr. POORE said that in almost all the cases he had reported the patients were in the hospital for a long time, and that where gouging had been performed the interval between the gouging and the excision was in some cases a year at least. He had given the patients all the chances of recovery he could, but, as suppuration had continued, the condition of the tarsus had not improved, and small pieces of bone had worked out, he had resorted to excision.

Dr. SANDS asked if it was good practice to leave a case for a year after an operation. Was it not rather desirable to follow one operation by another, with a view to removing all the diseased tissue as quickly as possible?

Dr. POORE said he had performed gouging in one case four times within a year. He had been very much disappointed in this operation. He had certainly expected to see some patients get well after it, but he had never seen such a result. It might be because he had dealt with young children, the patients having been mostly under four years of age.

Dr. LANGE recalled a very limited number of cases of tuberculous affections of the os calcis and astragalus in which the disease had been so limited that it had not been necessary to remove the bones entire. He had had one such case where the principal seat of the disease was in the bones of the ankle joint. There was also a tuberculous sequestrum in the os calcis, which was removed, and the entire shell of the bone left, and finally recovery took place. He thought that in a good many cases of tuberculous necrosis recovery would eventually take place after the removal of sequestra and scraping. It seemed to him that in Dr. Poore's cases a striking point was the difference between the reproduction of the os calcis and that of the astragalus; there had not been a reproduction of the astragalus. In some of his own cases of total excision of the ankle joint he had observed the same thing, and probably it had been this which had caused the amount of shortening in Dr. Poore's cases. He had twice excised the tarsal bones during his service in Bellevue Hospital, the first and second rows, and in one instance cut away also the surface of the os calcis and astragalus; in the other the extirpation was not so extensive, but the result was a good one, although the patient was an adult. The result in the first case he could not give, for the patient was removed from the hospital because she refused to submit to a secondary operation. The results of other surgeons were rather encouraging for operative interference—for instance, those reported by Neuber some years ago.

Osteo-sarcoma.—The PRESIDENT presented a specimen of large osteo-sarcoma, removed post mortem from a colored boy fifteen years of age. He had shown the boy to the society two years before. The history of the tumor was that it first appeared as a small swelling on the right side of the lower jaw eleven years ago. Its growth since that time had been uninterrupted. The boy remained in good health up to last July, when the interference with deglutition became so great that it was necessary to feed him *per rectum*. He died of inanition August 24th.

The microscopical examination was made by Dr. Frank Ferguson, who made the following report: "The tumor is an osteo-sarcoma with much fibrous tissue and fat. It arises from the right ramus and body of the lower jaw, to the right of the median line. Extending from this location is a mass of bone, the antero-posterior measurement of which is seven inches, and transversely it measures eight inches and a half. Vertically it measures four inches. This large mass of bone has crowded the left half of the lower jaw and a portion of the right half of the bone much to the left. The inferior maxillary bone is bent at the symphysis, forming an acute angle. An inch and a half of the body of the bone on the right side, containing two teeth, passes directly backward (from the symphysis) in the median line. The condyle of the right ramus is found just beneath the right external auditory meatus. The right half of the superior maxillary bone is much distorted. The last molar in this bone is half an inch below the floor of the right orbit, and three fourths of an inch from the median line. The œsophagus and trachea are pushed much to the left, being only an inch from the surface of the neck on that side. The neck extends directly backward, at right angles from the normal line of the vertebral column. The large mass of bone above described is covered by lobulated soft tissues, composed of fat, fibrous tissue, and numerous medium-sized spindle-form cells. The bone is simple compact bone tissue. The tumor is limited by a fibrous capsule. The greatest circumference of the tumor is twenty-nine inches. From the highest level to the most dependent portion of it it measures eleven inches. It weighs, as presented, seventeen pounds, three ounces and a half."

The Bacillus of Syphilis.—Dr. R. J. HALL presented the following report: In May, 1885, Dr. Süssgarten had published his pamphlet stating that by a new method, devised by him, of staining and bleaching syphilitic tissue he had found in sections of all the specimens examined, sixteen in all, a distinct bacillus; these bacilli were found in small numbers. In August, 1885, there was published ("Fortschritte der Medicin," Bd. 3, No. 16) an article stating the giaconic method of staining for the same bacillus. Both methods had been used by Mr. Freeman, under the guidance and with the supervision of Dr. Hall. The Süssgarten method, though more troublesome, was the more satisfactory. The statistics given below had been obtained from specimens stained by the Süssgarten method.

Seven specimens of syphilitic tissue had been examined. Five were primary—all typical hard chancres. Two were secondary—syphilitic papules.

Specimen No. 1.—No history. Sections received already cut. A typical hard chancre from the prepuce. Section No. 1: Found 1 bacillus in a cell; 2 bacilli in a cell; 3 bacilli in a cell.

Specimen No. 2.—No history. A typical hard chancre from the prepuce. Section No. 1: Found 1 bacillus in a cell; 1 bacillus in a cell; 3 bacilli in a cell. Section No. 2: Found 2 bacilli in a cell; 18 bacilli in a cell. In a flat cell in a condition of granular degeneration, no nuclei being visible, eighteen bacilli were counted, exactly corresponding to Süssgarten's description, and one or two dots which might be portions of bacilli partially concealed from lying obliquely. Section No. 3: Found no bacilli.

Specimen No. 3.—A typical hard chancre. Six weeks prior to August 11, 1885, a sore appeared on the peno-scrotal junction of a boy sixteen years old, with a simple balanitis. He had had connection one or two weeks before. Three weeks before the date mentioned the inguinal glands enlarged and an eruption appeared on the legs. There was a typical hard chancre, accompanied by a primary roseola on the abdomen and syphilitic buboes. The chancre was excised.

Microscopic Examination.—Section No. 1: Found no bacilli. Section No. 2: Found 2 bacilli in a cell, and 1 bacillus in a cell. Section No. 3: Found no bacilli.

Specimen No. 4.—A syphilitic papule was excised, August 11, 1885, from a boy aged nineteen, who five months before had had an extensive chancroid with phimosis, and had been circumcised. The lymphatics were now swollen. There were two characteristic syphilitic ulcers on the right forearm and several indurated papules on the scrotum. The specimen examined was a large indurated papule, ¾ inch in diameter, greatly resembling a primary chancre, on the line of circumcision. There were no other secondary symptoms. The induration on the penis was excised.

Microscopic Examination.—Section No. 1: 2 in a cell. Section No. 2: None. Section No. 3: None.

Specimen No. 5.—A typical hard chancre was excised from a man, aged thirty-six, which had first been noticed eight days before, the connection dating back four weeks. There was no eruption.

Microscopic Examination.—Section 1: Found none. Section 2: Found 1 bacillus in a cell; 2 bacilli in a cell; and 3 in three cells. Section 3: Found 1 bacillus in a cell.

Specimen No. 6.—A syphilitic papule was excised from a man, aged twenty-nine, who had had gonorrhœa eighteen months before, and had last had connection two months before. Two weeks before, he had noticed an indurated sore on the prepuce and enlarged glands in the groin. A few days ago there was roseola. All these symptoms were present when the induration was excised.

Microscopic Examination.—Section No. 1: Found 3 bacilli in 3 cells. Section No. 2: Found none. Section No. 3: Found 1 bacillus in a cell.

Specimen No. 7.—A syphilitic hard chancre was excised, September 21, 1885, from a boy aged nineteen, ten days after connection. Four days before, a sore had appeared on the prepuce, of the size of a split pea, having a hard base covered with yellowish material.

Microscopical Examination.—Section No. 1: Found 3 bacilli in a cell, and 2 in a cell. Section No. 2: Found none. Section No. 3: Found 2 bacilli in 2 cells.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of November 25, 1885.

The President, Dr. John A. Wyeth, in the Chair.

Cocaine Poisoning in a Cat.—Dr. H. J. Boldt presented the brain and medulla of a cat which had died in convulsions twelve minutes after an injection of eleven minims of a thirty-three-and-a-third-per-cent. solution of cocaine. The first effect noticed was a sort of leaping gait with dragging of the hind extremities, followed by convulsions. There was simulation of the Cheyne-Stokes respiration. The temperature in the rectum after death was 104° F. At the autopsy, made half an hour after death, the vessels of the pia mater in both brain and cord were much congested, and there was extravasation of blood in the fourth ventricle, also a small amount in the anterior part of the medulla, and there were minute extravasations throughout the brain. The lungs were collapsed, and contained no blood; the right ventricle of the heart was overdistended, the left one empty. There was congestion of the gray substance of the cord. Dr. Boldt said death seemed to have taken place from paralysis of the respiratory center.

Dr. M. Putnam Jacobi thought the phenomena pointed rather to contraction of the blood-vessels from vaso-motor irritation, and thus to death from obstruction to the pulmonary circulation.

The President said that respiratory and cardiac shock was more likely to occur from invasion of the surface in the neighborhood of the fifth nerve than in any other locality. He also spoke of the danger of using chloroform or ether after cocaine. A prominent surgeon had lost a patient by administering chloroform after the unsuccessful use of cocaine; and the same surgeon had told him of a similar accident after the use of ether following cocaine.

Carcinoma of the Uterus.—Dr. R. Van Santvoord presented a cancerous uterus, the disease having apparently commenced in the cervix and involved the body of the organ afterward. The patient had given birth to a child three days before her death. There was pigmentation of the intestines, omentum, retro-peritoneal glands, and broad ligament. The pelves of the kidneys and ureters were dilated; the ureters were somewhat obstructed by thick, dense fibrous tissue. The uterus was firmly fixed, the cervix had been eaten away, the urethra had been ulcerated into, and there was infiltration of the vagina and endometrium.

Tuberculosis of the Pharynx.—Dr. Van Santvoord also presented a pharynx, the seat of tubercular ulceration, removed from the body of an infant about two years of age, which had been admitted to Randall's Island Hospital about four months before its death with a large mass of enlarged glands under the angle of the jaw upon each side, accompanied by cachexia. A slight cough was noticed two months and a half before death, but physical examination revealed only a few râles over the lungs. A few days before death the child was thought to have some difficulty in swallowing, and a thin grayish coating was seen upon the larynx. The temperature was 102·5° in the evening. Death took place from exhaustion. The post-mortem examination showed the glandular enlargements upon each side of the neck to be due to caseous degeneration. The pharynx was roughened, and lenticular ulcers extended to some depth into the mucous membrane. The uvula was thickened and covered with granular elevations. The same roughened appearance was observed on the mucous membrane of the nasal cavities, the vault of the pharynx, and the convex surface of the inferior turbinated bones. There were two small ulcers upon the posterior surface of the larynx. There were miliary tubercles in the lungs and upon the pleural surfaces; there was a soft caseous nodule in the middle lobe of the right lung, together with a number of areas of broncho-pneumonia. There were also tubercles in the spleen, kidneys, liver, and intestines, and the retro-peritoneal and mesenteric glands were undergoing cheesy degeneration. Tubercular ulceration of the pharynx was a somewhat rare affection, although Dr. Mackenzie, of London, had reported a number of cases, and thought it was often mistaken for syphilitic disease.

The Lesions of Hog Cholera.—Dr. Van Santvoord also presented a stomach and large intestine illustrating the lesions of hog cholera. There was considerable gastritis, and at one point on the surface of the stomach there was a necrotic spot. This ulcer, which was like the characteristic ulcers in the large intestine, had a dark, dirty, sloughing center, with elevated edges. The process extended in different cases to a variable depth, sometimes reaching the peritonæum. The ileo-cæcal valve was swollen, principally on the side toward the colon, and contained ulcers; for about ten inches above the cæcum the mucous membrane was sloughing and the gut was intensely hyperæmic. In the descending colon there were enlarged solitary follicles, with depressed and slightly ulcerated centers, which were also apparent from the peritoneal surface. In some of the cases lesions were found in some other organs of the body, and in all there was some œdema of the lungs with some mucus in the bronchi. There was also in all of the cases enlargement of the retro-peritoneal and mesenteric glands.

Dr. T. M. Prudden said that Koch reserved his opinion regarding the micro-organism peculiar to hog cholera; that alleged

by Pasteur had been found by Koch in the septicæmia of rabbits.

Dr. D. B. Delavan said, regarding tuberculosis of the pharynx, that he had seen only three cases. In adults it was very painful. It was a rare affection, and resembled syphilitic ulcers, so that the general practitioner was liable to overlook cases which might come under his care.

SOCIETY OF MEDICAL JURISPRUDENCE AND STATE MEDICINE.

Meeting of October 8, 1885.

The Hon. W. H. H. Russell in the Chair.

Cremation.—Dr. William M. McLaury read a paper upon this subject. [See p. 633.]

The Chairman conceded to the author the utmost sincerity in his views, yet, with due deference to his opinions, he must beg to differ with him in his conclusions. Suppose for a moment that his theory was put into practice in this country, what would become of the sentiment with which we surrounded our dead? He further maintained that, religiously considered, the result of cremation seemed incompatible with the form of resurrection we were taught to believe in; and that, therefore, while Christian civilization prevailed, cremation would not. If it was true that the latter had been the popular method of disposing of the dead in ancient times, the custom should have been perpetuated—which it was not—in order that the fact might be made use of as an argument in favor of modern cremation. Regarding expense, that would have little or no weight with the rich as compared with their personal feelings; and fashion would undoubtedly render the accessories of cremation quite as costly as those of interment, thus making it in no way a less extravagant affair for the poorer classes.

Professor James L. Greenleaf continued the discussion by considering the subject from a sanitary point of view, though not to the total exclusion of sentiment. He said the grave-yard might be the cause of the death of a man's sons and daughters; and, were such the case, this fact would, in that man's mind, far outweigh all the sentiment associated with the place. There were probably few present who would not readily admit that cremation was preferable to burial, since it accomplished in a few hours what generally required years by the other method. At the same time he admitted that not all grave-yards—those, for instance, in the country—were inevitably disease-centers. The oxidation which took place in decay was identical with that in the furnace, though less rapid. A body free from contagion or infection might, therefore, be placed in a dry, well-aërated soil, and, without detriment to health, be intrusted to the ordinary destroying processes of nature. Even disease-germs might die in a dry, well-ventilated soil, though instances had been known where, probably under circumstances favorable for their growth, they had lived in the ground for years. Also, tests had been applied to the air above crowded grave-yards, and it had been found swarming with germs. He believed crowded cemeteries in populous districts to be unwholesome, even though no instances of disease could be positively traced to them. The laws of the Roman Empire made cremation obligatory, except in remote and thinly settled districts, where the practice of burial was allowed. This, he thought, would be a good example to follow to a certain extent, and suggested a compromise between exclusive cremation and general inhumation as an advisable and proper course to pursue.

The paper was further discussed by E. C. Kitchell, Esq., Professor A. L. Rawson, Dr. C. S. Wood, Dr. P. C. Cole, and others.

Reports on the Progress of Medicine.

PSYCHOLOGICAL MEDICINE.

By J. LEONARD CORNING, M. D.

Physiological Psychology.—Buccola ("Alienist and Neurologist") gives a long and comprehensive review of the arguments employed by contemporary psychologists to break the bonds of metaphysical traditions, in order to attain more objective results through the aid afforded by critical reasoning from experimental data. "Analysis of the facts that form the substratum and represent the mechanical conditions, by means of which sensation, thought, and consciousness are evolved, have now proved that the existence of a special *quid*, which lives in the organs and presides over them—an unextended substance, a pure essence, which has the characters of unity and simplicity—is an illusion purely subjective and abstract. It is the thesis of metaphysics which hunts after *noumena*, without perceiving that the universe is a pure phenomenality, that higher than phenomena thought can not soar without the risk of falling into abstractions, and that, in fine, the limits of knowledge are the limits of induction, and this can not give to us anything beyond phenomenal life."

In constructing our philosophies, we should not delve after substances and the intimate nature of things; what really constitutes a secure datum of cognition is the phenomenon. As Ardigo truly observes, there is no other kind of cognoscitive data, no other secure basis of scientific principles outside the experimental. This certainty is the unique result of the constant and uniform repetition of the same phenomena. The dualistic *a priori* method of regarding things peculiar to metaphysics is directly opposed to the spirit of exact science. The shadowy rules of metaphysics locate in every several thing two strata—one exterior and phenomenal, and one interior and substantive. To be more explicit, metaphysics perceives in everything a special essence, and certain phenomenalities which accompany this essence. In the essence, it maintains, there inheres a true and unchanging reality; in the phenomenon, on the other hand, there is but an uncertain, flexible reality. From the phenomenon it is impossible, therefore, on account of this very mutability, ever to derive such a code of laws as will correspond to the exigencies of the highest objective science. These metaphysical conceptions have entered and still persist in the domain of psychical facts, and their presence has given rise to a psychology at once hollow and barren of practical results. The unutterably grotesque and utopian problems to the solution of which this school of psychology has in vain addressed itself are the direct outgrowth of these same fallacious conceptions. "While the physical sciences, once also prostrated under the car of scholastic quidditics, have definitively deserted the field of philosophic necromancy and have been called sciences purely phenomenal, and, by the sole attentive study of facts, interpreting and inducting the laws which regulate the motions of nature alike in the immense sidereal spaces as in the infinitely small interstices of ether interposed between molecule and molecule, psychology, which ought to be the physics of human thought, has, on the contrary, remained entangled in the meshes of the absolutes and the essences tenaciously as the polypus to the rock, clinging to the old aprioristic method which shuns induction and experiment. And, while not only the physico-chemical sciences, but also biology, which should ever be the foundation of every psychical study, canceling from its pages the vital spirits, has, by the aid of comparative morphology and of embryogeny, luminously demonstrated the unbroken unity of the various organized forms, from the protoplasmic amœboid to the vertebratum, furnished with the richest specificized apparatus of nervous mechanism, and has, also by daring inductions, rendered legitimate by the general laws of nature, demonstrated the more marvelous unity of the two organic worlds, psychology has, on the contrary, persisted in the duality of spirit and matter, creating abstractions that explain neither the mechanism nor the laws of the production of mental facts." Up to our times, therefore, psychology has occupied an exceptional position in relation to other branches of science, inasmuch as it has failed to adopt the logic of induction, and has followed ratiocinative methods which represent at most but intellectual morbosities.

In our own time, however, a mighty change in the method of regarding psychological phenomena is discernible. If one follows attentively the rapid movements in the realms of modern science, one may discover with but half an eye that two grand conceptions dominate the entire development of psychology, transforming its contents: the theory of evolution, and the application of scientific methods to the elucidation of mental phenomena. The law of evolution, which explains the universal transformation from the homogeneous into the heterogeneous, is thus briefly formulated by Spencer: "Every active force produces more than a change; every cause produces more than an effect."

"As every fact succeeding proceeds from one anteceding, so all physical and mental facts, all biological and sociological, have been derived from antecedents which, traced back by induction from age to age, as far as can be reached by the secure laws of hypothesis, permit us to discover a simplicity greater in proportion to our greater distance from the present time, and show us, in the nebulæ, the first stage of the solar system; in the amœboid movements of the protozoa, the embryonal design of intellect; in the monera, the preparation of the vertebrate; and in the tribe of the savage, the germ of the constitution of civilized peoples." This vast evolutive conception, applied to mental phenomena, has given rise to a science substantially different from the ancient psychology, the usefulness of which was greatly lessened by the introduction into its methods of abstractions and *a priori* reasoning. By the application of the law of evolution to the elucidation of mental facts it has been possible to frame a scientific system of comparative psychology on the plan so ably unfolded by Mr. Herbert Spencer. "In fine, instead of that idolatrous image of science, which pretends to investigate the manipulations of mind from the static point of view, it substitutes the true personality of a science, psychogenesis, which studies the facts in their successive development." Modern psychology is not metaphysical; it does not seek information alone through the channels of pure introspective observation, but endeavors to ingraft into its system of research the methods of the exact sciences.

[Let us say rather that it *tries* not to be metaphysical, in so far that it seeks after phenomena, adopting in its quest after the latter the methods of the biological sciences. In its interpretation of these phenomena it is still hopelessly metaphysical in many regards.—J. L. C.]

Thus experiments may be performed in the psycho-physical domain; that is to say, by varying the physical conditions of the interior processes we may note the resultant psychological modifications. Looked at from this point of view, there are no psychological, but only psycho-physical experiments. "But the change which is determined by the varying of a condition does not depend simply on the nature of the condition, but also on that of the conditioned." Thus the psychical changes produced by varying the external influences will elucidate the interior phenomena, and, regarded from this point of view, psycho-physical experiments may also be denominated psychological.

[As the genetic method of research has grown apace in all directions, it is well to remember that, however interesting the revelations already or to be thence derived may be, they can never equal in practical importance the results derivable from psycho-physical experiments. —J. L. C.]

What, in the opinion of Dr. Buccola, forms, however, the truly new side of modern psychology is genetic research. "In what point of the animal series does psychical life commence? Between the amœba, which is an albuminoid clot with nervous elements, and the vertebratum, which has organs and instruments adapted to furnish to it the consciousness of itself, does there truly exist an abyss?" The old philosophic system, based on nebulous abstractions and deductions from *a priori* formulas, avoids this question with feelings well nigh akin to horror. On the other hand, biology, basing its method of research upon the comparison of organs and their functions, interprets the psyche as an "evolutive process, as a never-interrupted succession of gradations, which, from the plastid branches onward up to man, in whom the reflex act, which was manifested in the amœba without the diastaltic nervous arc, now invests itself with the complete aspect of perception." "Just as vegetable physiology, by descending to the mosses and the *Conferva*, and unveiling the organic mechanism of the plant in the cells and fibers which are associated and disposed in a thousand ways, succeeds in constructing the organic structure of large cotyledonous trees, so the majestic tree of human thought can never be comprehended unless regard is had to the formless germule of the psychical life of the zoöphyte, and ascending evolution is followed up in the animal series."

[Dr. Buccola's paper is the best review of the present spirit of modern (physiological) psychology with which we are acquainted. It will richly repay perusal by those who are anxious to place themselves in accord with the principles of research which are exerting such a vast influence in the domain of modern philosophic thought. Dr. Buccola is something more than a mere mechanical observer of phenomena. Throughout his paper there are ever-recurring evidences that he is endowed with a perspicuity and power of analysis which come to us as a welcome intellectual addition to a discipline which, thanks to the efforts of an army of pedants and hair-splitters, has received at the hands of practical men the cognomen of the "awful science."—J. L. C.]

Post-neuralgic Insanity.—Dr. C. H. Hughes (*Ibid.*) records two interesting cases of psychical aberration consecutive to neuralgia. In the first case, that of a lady, all branches of the seventh pair were implicated. Local treatment with galvanism, etherization, etc., finally caused almost complete cessation of the pain. Thirty days before these results were obtained all opiates were discontinued. Some days after this, symptoms resembling those of acute delirious mania made their appearance. These lasted six weeks, being finally dissipated by persistent treatment with iron, arsenic, galvanism, and chloral hydrate.

In the second case, that of a gentleman formerly an officer in the navy, the mental symptoms were developed after a severe attack of sciatica. The relief of the latter was finally accomplished, after four weeks, by prolonged and frequently repeated applications of powerful galvanic currents. With this relief from pain there was no greater quiescence of the mental faculties; but, on the contrary, restlessness, insomnia, and aggravated psychical disturbance became predominant. Treatment did little to modify this morbid condition; but, after running a course of seven weeks, the maniacal symptoms disappeared. The rest obtained during this interval was the result of sedatives.

The condition of this patient at the time the psychical symptoms made their appearance was one of "neuratrophic or neurasthenic typhoid."

General Paralysis at an exceptionally Early Age.—Dr. E. Régis ("L'Encéphale") published in 1883 the details of a case of general paralysis occurring in a boy of nineteen years. In the last number of the same journal he now gives the history of a most interesting case of the same malady, occurring in a boy of seventeen years of age. The patient, a natural child, was born at Bordeaux on the 9th of November, 1864. His father, who, in spite of the irregularity of his child's birth, was most solicitous for the latter's welfare, is a man of forty-seven years of age, married, intelligent, and possessing a legitimate child two years of age. He has been troubled for some years with rheumatic gout, and his father and one of his brothers were victims of this disease. His mother is a woman about forty years of age, intelligent, in fair health, but of nervous temperament. The maternal grandmother died at the age of fifty-four years in a condition of profound psychical disturbance, with suicidal tendencies of four years' duration, melancholia, refusal of food, etc.

This, in brief, is the genealogy of the patient. The latter has never had an infantile cerebral affection of any kind. At school he gave evidence of intelligence; but at the age of seventeen years, without the slightest warning, ptosis of the right eyelid became developed, and persisted until his death. From this moment his intelligence began to suffer and his memory to fail him; he forgot what he had already acquired, and at last he was sent home by his school-master. Some months after this, his condition meanwhile remaining about the same, he was attacked by an outburst of maniacal excitement upon slight provocation, suffered from persistent insomnia, was exalted in conduct, and masturbated continually. Finally his speech became characteristically affected. On the 4th of August, 1883, he was placed in an asylum. At this time the symptoms of general paralysis were well developed: his lips and tongue were the seat of characteristic tremor, his speech was profoundly affected, the pupils were uneven and sluggish, the right eyelid drooped, the hands and feet were moved about

awkwardly, and before long his sphincters became completely relaxed. As to his mental symptoms, it was observed that his intellect was exceedingly feeble, his memory was almost gone, he was perfectly unconscious of his condition, and was oblivious to what transpired about him. There were no delirious symptoms, properly speaking.

As, from conversation with the mother, the existence of a syphilitic element in the case was suspected, a rigorous specific treatment was ordered in the form of inunctions. This treatment was badly borne; indeed, he seemed to get worse under it. Shortly afterward he was taken home, and, under a derivative and purgative treatment, his condition was considerably improved for a few months. Soon, however, he relapsed into a condition of cachexia, became bedridden, and was afflicted with bed-sores, frequent bleedings at the nose, and atrocious pains in the head. In December, 1884, he died. No autopsy was permitted.

The author concludes that where general paralysis occurs before the twenty-fifth year the fact is owing to some powerful predisposing factor, such as heredity, syphilis, alcoholism, traumatism, some form of general diathesis, in short, which tends to give rise to the anatomical conditions of the brain found at the epoch of mature life.

The Curability of Insanity.—Dr. Pliny Earle ("American Journal of Insanity") adds a most scientific statistical study to the literature of this subject. Some of his conclusions possess much interest from a theoretical and practical point of view. Thus, he observes that, so far as the statistics presented are an indication, the recoveries in British asylums, both in recent cases and of all patients admitted, exceed the recoveries in American institutions by between eight and nine per cent. The most important general conclusions to be derived from the statistics included in this paper are, first, that the old allegation of curability in a very large majority of recent cases is not sustained, and that a failure to sustain it is more apparent and more striking than at any antecedent time; and, secondly, that the percentage of reported recoveries of all cases received at the hospitals in this country still continues to diminish. The author of the paper pertinently observes that the diminution is perhaps in part attributable to the admission of a larger proportion of chronic cases and of cases of greater degeneracy from their origin, in part to a more stringent interpretation of the meaning of the word recovery, and to greater conscientiousness in the compilation of statistics.

Exactness in Psychological Nomenclature.—Dr. Orpheus Everts (*Ibid.*), in an article entitled "New Wine in Old Bottles," enters a protest against the confusion which has arisen from a lack of definiteness in expressions employed for the communication of ideas in psychiatric science. The new conceptions growing out of the application of the laws of physiological psychology demand a revision of the terms employed by the older metaphysical philosophy. The well-known illogical applications of such words as "will," "emotions," etc., are cited as illustrative of the author's position. [While we readily admit that the confusion of terms deprecated by Dr. Everts has a real existence in fact, we are compelled to acknowledge that the ground for such confusion is ample. It is the outgrowth, in a word, of the extremely rudimentary condition of physiological psychology itself. In truth, as Herbert Spencer observes: "Though accumulated observations and experiments have led us, by a very indirect series of inferences, to the belief that mind and nervous action are the subjective and objective faces of the same thing, we remain utterly incapable of seeing, and even of imagining, how the two are related. Mind still continues to us a something without any kinship to other things; and from the science which discovers by introspection the laws of this something there is no passage by transitional steps to the sciences which discover the laws of these other things."—J. L. C.]

Race and Insanity.—Dr. Joseph G. Kiernan ("Journal of Nervous and Mental Disease") has made a series of interesting studies with a view to ascertaining whether the insanity of the negro is tinged by certain psychical tendencies—such, for example, as those seen in the voodoo superstitions and in the periodic attacks of sexual furor which are such characteristic features of the dusky race. As the author truly observes, the attacks of sexual furor exhibited by negroes, especially in the spring, bear a close resemblance to the corresponding phenomena displayed by the elephant and the bull. In order to test the question as to how far insanity in the negro is characterized by the phenomena just referred to, the author has carefully collected the statistics of a number of cases of paretic dementia occurring in negroes. From a careful analysis of these cases he is led to conclude "that the psychical peculiarities dormant in the race crop out very prominently in these cases, and it would appear certain from these that the question about the influence of the superstitions of the race must be answered in the affirmative."

Onomatomania.—Charcot and Magnan ("Archives de neurologie") have, under this somewhat formidable designation, drawn attention to a series of mental symptoms in which a name or a word plays a prominent part. In order that the preoccupation with the word shall attain such dimensions as to provoke positive anguish, and that such preoccupation shall repose upon an urgent active seeking after the word—upon a possession, an impulse—it is, of course, necessary that the psychological substratum should possess particular attributes. This assemblage of conditions, like that present in *folie de doute*, perversions of the sexual feelings and inversion of the latter, fear of pins, dipsomania, etc., can only be developed in those who are predisposed. "All these conditions, so numerous and so variable, confounded under the designations of insanity with consciousness, reasoning mania, mania without delirium, pseudo-monomania, etc., are only psychical stigmas of hereditary insanity." Moreover, these episodical conditions may be determined by the most trivial causes; the remembrance of a trifling incidental circumstance may give rise to the agonizing search after the name. In order to thoroughly appreciate the part which the word is capable of playing in the preoccupations of those afflicted by hereditary predisposition to mental weakness, it is necessary to examine the principal conditions to which it may give rise: "1. The harrowing search after the name or the word. 2. Continuous besetting of the mind by the word which imposes itself, with an irresistible impulse to repeat it. 3. The particularly portentous significance of certain words occurring in the course of conversation. 4. The preservative influence of certain words. 5. The word become a veritable solid body to the patient, inadvertently swallowed, pressing heavily upon the stomach, and capable of being rejected by expectoration."

Miscellany.

The International Medical Congress.—The following "special announcement" has reached us: "The Executive Committee of the Ninth International Medical Congress, to be held in the city of Washington, D. C., commencing on the first Monday in September, 1887, having accepted, under Rule 10 of the Committee on Preliminary Organization, the charge of the business of the Congress, hereby give notice to the members of the medical profession that they have been actively engaged upon, and have now nearly completed, the arrangements for this meeting; and they anticipate the hearty co-operation of the profession everywhere in developing this great scientific and humanitarian assembly.

"By order of the Executive Committee.

"HENRY H. SMITH, M. D., Philadelphia,
"*Chairman of Executive Committee.*
"NATHAN S. DAVIS, M. D., LL. D.,
"*Secretary-General of the Ninth Int. Med. Congress.*
"CHICAGO, *November* 24, 1885."

The International Medical Congress of 1887.—A meeting of members of the medical profession interested in the International Medical Congress in 1887, to which prominent medical men from a number of cities were invited, was held at the Hall of the College of Physicians, Philadelphia, December 4, 1885, Dr. D. Hayes Agnew in the chair.

It was stated that official notice had been given of the election, as members of the present Executive Committee of the Congress, of Dr. J. S. Billings and Dr. J. M. Browne, of Washington, D. C.; Dr. Christopher Johnston, of Baltimore; Dr. George J. Engelmann, of St. Louis; and Dr. J. M. Da Costa and Dr. William Pepper, of Philadelphia.

A general and strong expression of opinion was made in support of the American Medical Association and its Code of Medical Ethics, and sincere regret was expressed that hasty action on the part of the association, and the introduction of false issues, had imperiled the success of the Congress. It was made entirely evident, however, that the acceptances of the above elections would not be regarded as affording any adequate guarantee for the future scientific conduct of the Congress, and, consequently, would not be followed by any co-operation on the part of the leading members of the profession now unwilling to join in that work. As an evidence of the earnest desire which is felt for the restoration of harmony upon this subject, and for the reorganization of the Congress on a basis which would command general support, and thus insure success, the view was unanimously expressed that if the present Executive Committee should unite with them the Original Enlarged General Committee, and recommence the organization *de novo*, this course would insure the desired result.

The late Dr. Samuel S. Clark, of Belvidere, N. J.—We have been asked to publish the following:

"The Board of Managers of the State Asylum for the Insane at Morristown, N. J., learn, with the deepest feelings of sorrow, of the death of their honored Vice-President, Dr. Samuel S. Clark, which occurred at Belvidere, on Monday, the 23d ult., at the age of sixty years.

"Dr. Clark came of a distinguished ancestry, from whom he inherited those sterling qualities which made his life so useful and honored. His grandfather, the Rev. Joseph Clark, left the pulpit to enter the Revolutionary Army, and served with distinction on the staff of General Washington. His father, the Rev. John Flavel Clark, was also a distinguished Presbyterian clergyman, and one of the founders of the American Board of Foreign Missions, and subsequently became one of the faculty of Princeton College. With such ancestry it was but natural that Dr. Clark should be the noble man that he was.

"He was born at Flemington, N. J., November 8, 1825, and entered Princeton College in 1841. After a three years' course in that institution he entered and graduated from the Medical Department of the University of New York, and for nearly thirty-seven years practiced medicine in Belvidere. His kindness of heart, his faithfulness as a friend, his wisdom as a counselor, his tender sympathy and skill as a physician, endeared him to the homes and families in the bounds of his large practice. His clear mind, his fine culture, his habits of careful study, and his acquaintance with the best results of science, placed him in the front rank of his noble profession. He was active and public-spirited as a citizen, always promoting the best interests of the community in which he lived.

"As a member of the Board of Managers he was firm in his convictions of right, yet considerate and forbearing with those who differed with him. Withal, he was modest and unassuming, and always a gentleman. He was one of the most companionable of men, and his fine social qualities endeared him, not only to his associates in this board and to the masses with whom he came in contact, but to eminent men in all professions throughout his native State. More than an ordinary man has fallen; a happy home has been made desolate, and a devoted wife and daughter, upon whom his fondest affections were centered, mourn for one whose companionship was more precious to them than all other earthly treasures. We tender to them our deepest sympathy We record this tribute to his memory in our book of minutes, and request our secretary to transmit a copy of the same to his sorrowing family."

The Mutter Lectures.—The first two lectures of the Mütter course, by Dr. Henry F. Formad, were given before the College of Physicians of Philadelphia on Tuesday and Friday evenings, the 8th and 11th inst. The succeeding lectures are appointed for December 15th, 18th, and 22d, and January 5th, 8th, 12th, 15th, and 19th. The subjects are: "Morbid States as influenced by Embryonal Development, Anomalous Structural Peculiarities, Injuries, and the Effects of Lower Organisms, with Special Reference to Surgical Pathology."

The New York Academy of Medicine.—The Section in Surgery will meet Monday evening, the 14th inst., at 8 o'clock. The subject of "The Indications for Laparotomy in Penetrating Stab or Shot Wounds of the Abdominal Cavity" will be discussed by Dr. Bryant, Dr. Wright, Dr. Weir, Dr. Dennis, and Dr. Wyeth. The Section in Theory and Practice of Medicine will hold a meeting the following evening at the same hour. Dr. H. N. Heineman will present the subject of "Auscultatory Percussion."

The Health of the State of New York.—According to the State Board of Health's "Monthly Bulletin" for October, the total number of deaths reported was 5,680, the percentage among infants being 32·6. In every thousand deaths there were 204·22 from all zymotic diseases, 26·59 from typhoid fever, 57·04 from diarrhœal diseases, and 75·53 from croup and diphtheria. There were five deaths from small-pox.

The Health of Michigan.—It appears by a circular issued by Dr. Henry B. Baker, the secretary of the State Board of Health, that during the month of November diphtheria was reported from sixty-three places, typhoid fever from thirty-four, scarlet fever from thirty-nine, and measles from six.

The Philadelphia Polyclinic.—We learn that the Polyclinic's new building, at the corner of Broad and Lombard Streets, will soon be ready for occupation. Owing to the increased attendance, its present quarters, at the corner of Thirteenth and Locust Streets, have been found inadequate. The new building will contain hospital wards and private rooms for paying patients, and it is intended that greater attention shall be paid to the out-patient service. It is announced that the journal edited by the faculty will be doubled in size after the first of the year.

A New Spanish Journal.—We have received the first number of the "Gaceta del Hospital Militar," a monthly journal published at Guadalajara. It is largely devoted to statistical and sanitary matters connected with the army, besides which there is the history of a case of chyluria ameliorated by dietetic treatment.

"Ominico" as an Antiseptic.—Dr. Henry F. Beam, of Johnstown, Pa., lately reported to the Central Medical Association of Pennsylvania the history of a case of oöphorectomy in which a solution of mercury bichloride was used at the time of the operation, a compress wet with it being applied over the wound. The next morning he found that considerable hæmorrhage had taken place during the night, that the compress was saturated with blood, and that the parts gave out "a nasty cadaveric odor." Two sutures were removed, and a considerable amount of coagulated blood was turned out with the handle of a scalpel. The parts were then thoroughly cleansed with "ominico," fresh sutures were applied, and a compress saturated with "ominico" was laid over the wound, and the subsequent progress of the case was in every way favorable.

Ozoniferous Essences as Antiseptics.—"Listerine," says the "Sanitarian," "possesses essential properties analogous in their effects to the ozoniferous ethers so highly recommended by Dr. Benjamin Ward Richardson and others as deodorizers and disinfectants for the sick-room, and should be used in the same way—sprinkled over handkerchiefs, garments, and the bed-linen of fever cases. Mantegazza, 'On the Action of Essences and Flowers in the Production of Atmospheric Ozone, and on their Hygienic Utility' ('Rendiconti del Reale Instituto Lombardo,' vol. iii, fasc. vi), as quoted by Fox on Ozone, reports that the disciples of Empedocles were not in error when they planted aromatic and balsamic herbs as preventives of pestilence. He contends that a large quantity of ozone is discharged by odoriferous flowers, and that flowers destitute of perfume do not produce it. Cherry-laurel, clove, lavender, mint, lemon, fennel, etc., are plants which develop ozone largely on exposure to the sun's rays. Among flowers, the narcissus, heliotrope, hyacinth, and mignonette are conspicuous; and of perfumes similarly exposed, eau-de-cologne, oil of bergamot, extract of millefleurs, essence of lavender, and some aromatic tinctures. He also points out that the oxidation of the essential oils, such as nutmeg, aniseed, thyme, peppermint, etc., is a convenient source of ozone, and concludes that the ozoniferous properties of flowers reside in their essences, the most ozoniferous yielding the largest amount of ozone. It is of such aromatic essences that Listerine is composed, and hence its efficacy under the circumstances indicated."

REMARKS UPON THE CLIMATE OF FLORIDA.*

BY J. C. WILSON, M. D.,
PHILADELPHIA.

"Si la curabilité de la phthisie n'existait pas, il faudrait l'inventer, ne fût-ce que pour consoler le malade et pour justifier le médecin."—G. SÉE.

WHATEVER may be the ultimate outcome of the systematic investigation of the effects of different climates upon chronic lung diseases now being carried on, whatever the mutations of opinion, whatever the changes of fashion, Florida is to-day, and is long likely to be, the *most popular* of American winter resorts.

The popularity of this region as a resort for invalids, and especially for those suffering from diseases of the lungs, had its beginnings with the medical profession, and is based upon well established and easily verified facts relating to the equability of the climate and the low death-rate from consumption among the residents of the State. Its popularity with valetudinarians and the non-invalid classes, while also largely dependent upon the peculiarities of its fortunate winter climate, is enhanced by the practicability of continuous out-door life, the facilities for fishing and hunting, the sub-tropical vegetation of many regions in strong contrast with the snow-bound landscape of the North, and the ease and speed with which it can be reached. To these attractions add the excitement which attends the opening up of new territory, the development of new industries, opportunities for investment, chances for speculation, a most fertile soil upon which may be grown the widest range of fruits, vegetables, and staples, that *ignis fatuus* of northern capital, the orange, and it is easy to comprehend the enormous and increasing annual afflux of northern people to Florida at the beginning of winter. It is also easy to understand why a percentage of such visitors, both of the invalid and the non-invalid classes, and by no means inconsiderable, become permanent residents.

But the popularity of Florida has not grown in the profession as among the people. Medical men, anxious for the best results and seeking to act without prejudice, have in recent years become cautious as to whom they shall send to winter in Florida; have often acquiesced in such a plan rather than ordered it, and this not infrequently with serious misgivings. In the absence of statistical evidence bearing upon the effects of the climate upon invalids of all kinds—evidence difficult to obtain in regard to climate-treatment under the most favorable circumstances, quite impossible upon any adequate scale in this instance—it is not easy to explain at first sight the present guarded attitude of the profession.

But a closer examination of the conditions reveals some warrant for it. In many instances it has grown out of repeated unsatisfactory and disappointing results in particular cases. In others there has arisen a feeling of uneasiness as to the sanitary arrangements in over-crowded, restricted localities wholly lacking natural facilities for drainage. Again, the advantages of other and diametrically different climates have been urged upon the profession with an ability and pertinacity which have carried conviction sometimes even in the absence of proof.

Germain Sée, in his recent work upon "Bacillary Phthisis," divides the climates appropriate to the treatment of consumption into three categories:

1. Warm maritime climates,
2. High-altitude climates, necessarily cold,
3. Warm low climates not maritime,

and regards the first two of these as embodying all that is essential in the climate-treatment of this disease—namely, purity of the atmosphere, the more or less complete absence of dust and microbes in the air, abundant light, and ozone. From the standpoint of this observer, the fact that the low barometric pressure of high altitudes and the increased pressure of the sea-coast, acting so differently as they do upon the function of respiration, are alike favorable, is only an apparent contradiction. On the one hand, the increased oxygen of low levels is unfavorable to the biological necessities of the bacillus; on the other hand, the rarefied atmosphere freely ventilates the lungs and interferes with the multiplication of this microbe.

I confess to an inability to view the subject in this simple manner. To me phthisis, alike clinically and pathologically, is a complex malady, and climate an entity, the sum of many factors, variations in any one of which may modify the result, and therefore too complex for any save the most cautious generalizations.

The meteorological phenomena of various regions are constantly marshaled before our attention as all-important in determining the nature of the climate, and a subordinate value is often assigned to such matters as soil, drainage, aspect, and exposure to or shelter from particular winds. But the investigation of the climate of different localities from the standpoint of the therapeutist demands that every element entering into its composition (and their number is many) should receive due consideration. In fact, local conditions are so important that wide variations of climate within narrow geographical limits are constantly encountered—I was about to say are the rule rather than the exception. This statement is certainly true of the Florida peninsula. The regions of the State now readily accessible to travelers of every kind, including all invalids who have anything to expect from climate-treatment, comprise four distinct strips of territory, which differ from each other in their climate in essential particulars. I speak now of the peninsula of Florida, and exclude from consideration the main-land contiguous with Georgia and Alabama, which has not up to the present time, to any great extent, attracted the attention of invalids.

These four strips of territory extend in a general north and south direction, and are nearly parallel to each other and to the long axis of the peninsula. They are:

* Read before the American Climatological Association, May 28, 1885.

1. The Atlantic seaboard,

2. The St. John's River,

3. The elevated pine lands forming the water-shed of the State, and

4. The Gulf coast.

A brief study of the general characteristics and the special peculiarities of these regions may serve to point out some of the sources of disappointment in the past, the real advantages for a wider range of patients and their better distribution at present, and the opportunities for a more scientific and more extensive employment of the resources of the State in the climate-treatment of disease in the future.

The two great characteristics of the climate of all these regions alike, in fact of that of the whole peninsula, are mildness and equability. These traits are due to causes for the most part well understood, namely, the sub-tropical geographical position of the peninsula and its situation between the waters of the Gulf Stream on the one hand and the Gulf itself on the other; and its surface configuration, marked by low levels, the average altitude being about sixty feet, and the absence of abrupt elevations or mountains of any kind.

The peculiarities of the different regions depend upon conditions which are purely local.

It is obvious that the greater portion of the territory already accessible to railroad travel, including the fertile "hummock lands," the savannas, and many other regions adapted to agriculture, are unsuited to the needs of invalids, and that a few localities only are adapted to the requirements of health resorts.

1. The Atlantic Seaboard.—The principal stations are Fernandina and St. Augustine. They enjoy the advantages and suffer from the disadvantages of a climate essentially maritime. The life is agrecable, the amusements are diversified; many patients steadily improve at these places. On the other hand, a small number suffer from the abrupt alternations of the land- and sea-breezes, and from a certain sense of excitement or nervous tension which they attribute to the "*stimulating*" effect of the sea-air. This class includes many neuralgic and neurasthenic subjects, those who have a disposition to bleed, and those who have fever. Moreover, these stations are subject to the northeast storms which occasionally prevail here as elsewhere on the Atlantic coast, and are the cold, wet storms of Florida. Sidney Lanier quaintly remarks that the climate of Florida is nearly perfect, but that it has a *northeast nick* in it.

Farther south upon the seaboard the beautiful Indian River country, sheltered as it is by Merritt's Island, is as yet inconvenient of access, and lacking in suitable accommodations for invalids.

For those who are equal to the requirements of an out-door life and fond of "roughing it," this region has special attractions.

A lad of eighteen, the last of a phthisical race, went down there last autumn because he had orange interests to look after, and brought back this spring eighteen pounds of hard additional flesh and more than strength in proportion. His complaint was that he was "hungry for milk"—a hunger complained of everywhere in Florida.

2. The St. John's River.—I speak of this beautiful stream or chain of lakes with its thirty-eight stations between Jacksonville and Enterprise, a distance of one hundred and forty-six miles, with hesitation, lest in expressing a personal view, which I believe to be well founded, I may do any interest a wrong.

These stations are every winter crowded with the sick and their friends. Lured by its marvelously beautiful scenery, its facilities for out-door life, its clear and almost currentless waters, its gentle air, the consumptive spends his winter along this river in tranquil dreams of better health and strength in the spring. It is an ideal land, and its atmosphere is drowsy with the perfume of its flowers. But what of its climate? Neither the advantages of high, cold stations, nor those of the sea; neither dryness on the one hand nor ozone on the other. It is essentially a sub-tropical lake climate, in many districts a marsh climate. Such a climate as this finds place in no classification of winter or summer stations for the sick. Doubtless there are patients who do well. The open-air life counts for much. It is far better than that of the office or the shop. But some of whom I have knowledge have fared the worse for the seductive climate of the St. John's River. I will not speak of fever except to say that the danger of intermittents constitutes one of the real objections to several of these stations.

Until within a brief time these two strips constituted the accessible regions of Florida for the great majority of invalids and tourists. Some persons could not stand the coast climate; that of the river had dangers for all. Thus the physician set his face against Florida and sent his patients to Colorado, to New Mexico, to California, to Arcachon, to Pau, the Riviera, Capri, the Tyrol, the Engadine, the Cape of Good Hope. Such are the journeys which the rich man with damaged lungs is called upon to make in search of the health he seldom finds. The poor must stay at home. And some have been sent to Aiken, the Georgia Sand Hills, to Thomasville; and on the whole they have done better.

But within a year the railroad system of the State has again pushed its way across to the Gulf and opened up new regions of which the climates, retaining the cardinal traits of mildness and equability—nay, more, excelling in these—possess peculiarities and advantages of their own.

Of these, as we proceed westward, the first region is found in

3. The Elevated Pine Lands of the Water-Shed.—This divide extends from the Okefinokee Swamp in Georgia southward and somewhat to the east, with an average altitude of about two hundred feet, and occasional ridges reaching an elevation of three hundred feet. Between this main ridge and the Gulf there is a second line of elevation known as the Sand Hills, which attains a height of about one hundred and twenty feet. At many points along the line of the South Florida Railroad these lands are being settled and developed with the activity of a new oil or mining country. Exact meteorological data are not yet collected, but the climate of these pine lands is in many respects not unlike that of Aiken or Thomasville, but much milder and more even. The soil is sandy and deep, with good natural

drainage facilities; it is adapted to market gardening, and, when properly cultivated, sufficiently productive. The pines branch high and afford little obstacle to the free movements of the atmosphere. The summers are bearable, and many invalids are becoming permanent settlers. It is safe to predict for this region a useful future in the climate-treatment of diseases of the chest.

Finally, 4. The Gulf Coast claims our attention. Here we find the perfection of the warm maritime climate—from Cedar Keys to Punta Rassa, a coast-line much broken, deeply indented, and of rare beauty. This region rejoices in a climate which possesses, in an exceptional degree, the qualities of equability of temperature, purity of atmosphere, and comparative dryness. Stretches of hummock land alternate with sandy reaches of some elevation, and often covered with an open growth of pine. Along the edges extend narrow beaches shelving gradually into the limpid waters of the Gulf; overhead is a summer sky.

The mean temperature for the five winter months, during a period of five years, at the United States Signal Station at Punta Rassa, is shown in the following table:

November	69·4
December	64·6
January	64·8
February	66·1
March	68·8
Mean for five months	66·7

The maximum and minimum temperatures for the same months, in the years 1878–1879, are here set forth:

	Max.	Min.
November	83·7	46·7
December	76·2	42·3
January	79·3	46·7
February	79·1	47·6
March	82.6	49·7
Mean for five months	80·7	46·6

The movement of the air is, as a rule, moderate but continuous—a factor of much importance in climate. The influence of the sea and of the abundantly wooded shores, where grow in plenty the pine, the palm, and the cypress, brings about an atmospheric state at once free from inorganic and organic dust and rich in ozone. In this aseptic air, notwithstanding the warm temperature, putrefaction goes on but slowly, and meats hung out are said to remain free from taint and to undergo a slow desiccation without decomposition. This is doubtless also largely due to the dryness of the atmosphere.

The rain-fall is small. At Punta Rassa, during the five cold months, it is given in inches and hundredths from the statistics of the Signal Service as follows:

November	1·62
December	1·08
January	2·31
February	1·79
March	·83
Mean for five months	1·52

The mean of the maximum and minimum temperatures of the water of the ocean bottom at Punta Rassa, for the five winter months during five years, from 1878 to 1883, is here shown:

November	72·8
December	67·2
January	63·6
February	68·1
March	73·0

The advantages of this region as a winter station have long been known. The Government Reservation of Fort Brooke, at Tampa, was formerly used for this purpose. Some years ago Dr. Levis, of Philadelphia, published an admirable paper describing the climate and life of the Gulf Coast. At the meeting of the American Medical Association this year at New Orleans, Dr. Van Bibber, of Baltimore, again called the attention of the profession to it, with a valuable suggestion as to the hygienic principles to be regarded in the improvement and development of localities designed to be used as health resorts.

The obstacles to its settlement and growth hitherto have been connected with difficulty of access and want of means of communication—a difficulty no longer existing. Railroad and steamboat facilities are to-day ample, and the tide of travel has set toward this region. Towns and settlements are springing up at many points. Large investments of capital have led to an extended knowledge of the advantages and resources of this portion of the State. Suitable accommodations for invalids and tourists are projected in various localities. The establishment of sanitaria and other similar institutions upon a large scale in regions previously unsettled affords opportunities for measures of hygiene elsewhere practically unattainable. Danger of over-crowding and errors of drainage may be at least avoided.

Among many excellent localities, the high strip of pine land which extends as a peninsula between the Gulf and Tampa Bay, terminating in Point Pinellas, has great natural attractions. Its dry, sandy soil, its comparative elevation above the water-line, its protecting reefs and islands, its narrow but smooth beach, its clear waters, abounding in fish, and its natural semi-tropical vegetation, adapt it in a remarkable degree to the purposes of a health resort. The Statistical Reports of the Surgeon-General's Office show that the climate of Fort Brooke, across the bay from Point Pinellas, possesses in a high degree the favorable characteristics of this general region. The thermometric range is "less than at any other point in the United States, with the exception of the coast of southern California." The mean annual temperature is 58° F., with extremes of 92° F. in summer and 34° F. in winter. I have been informed by trustworthy observers that the temperature at Point Pinellas is some degrees higher than this, that the extremes are less, and that frosts are practically unknown. In fact, the Point has been spoken of as the "Frostless Pinellas." Like the rest of Florida, this region enjoys complete immunity from the sudden variations of temperature and violent storms which occur in the vicinity of mountain ranges. The prevailing winds are from the south and west; northeast storms are unknown except at the equinoxes; northwest storms, which correspond to the "northers" of Texas, are occasionally felt. These are the cold, dry storms of Florida. The settle-

ments upon Point Pinellas at Big Bayou are exempt from every form of malarial disease. The water in the bay is always warm, the beaches are of gradual slope, the ebb and flow of the tide only about twenty inches; bathing is therefore practicable at all seasons and free from danger.

In conclusion, it may be affirmed that the climate of Florida, though possessing the attributes of warm maritime climates in general, is much diversified and is, in its various regions, adapted to the requirements of a large class of invalids both for the winter season and as a permanent residence.

DISCUSSION.

Dr. Tyndale said the use of the terms mildness and purity, and others, in Dr. Wilson's paper gave him occasion to say what he might have said in connection with Dr. Denison's paper. Such terms were negative expressions, and were implied in the positive ones used in Dr. Denison's paper. Dryness, equability of temperature, and elevation implied all the other qualities or elements of climate, such as sunshine, wind, and electricity, for the latter were dependent upon the former. The terms mild, soothing, etc., denoted sensations only. He would not compare the effects of dryness and elevation, which were inseparable, with those of equability of temperature, but would say that there were statistics to show the influence of these climatic elements upon the human system, and it was these positive facts which were of value in the study of climatology. Sunshine, an implied quality of these three, was to be found in connection with equability at the sea-shore, and in connection with dryness and elevation at inland altitudes. Sunshine had two qualities, that of abundance and that of intensity. Abundance, there being a great many clear days, was common to the sea-shore and to inland stations, but intensity of sunshine was present only at inland altitudes, where there was no obstruction in the atmosphere to the passage of the rays of light. Of other elements of climate he knew nothing of the effect upon the human body, except as they were negative, interfering with comfort. In this regard wind was the principal factor, having the effect of rapidly cooling the body and creating dust and general discomfort, and was generally an attribute of dryness and elevation rather than of equability and moisture. If we had to choose in any given case from among the three elements of climate mentioned, dryness, elevation, and equability, which included other conditions, such as electricity, ozone, etc., it was better to choose the first and second and leave out the third, for the third without the first could be of little benefit. In other words, it was better to choose dryness in connection with elevation, and forego equability, than to choose equability and forego dryness and the effect of elevation or reduction of pressure. In that respect he would say that he believed the peninsula of Florida had only the element of equability with abundance of sunshine but without intensity.

AN ACCOUNT OF A SUIT FOR DAMAGES

IN A CASE OF ALLEGED INJURY BY A BLOW ON THE EAR.

By GORHAM BACON, M. D.,

and D. B. ST. JOHN ROOSA, M. D., LL. D.

(*Concluded from page 663.*)

Re-direct Examination.—My testimony is based upon my experience in similar cases, which leads me to believe that this boy's condition had existed three or four years. I found the left nasal passage more obstructed, more inflammatory material thrown out there than on the right side. He could breathe more freely through the right nostril than through the left one. In that way I accounted for the inferior hearing on the left side. The Eustachian tube was not so pervious on that side. In my opinion, it is impossible for an expert opinion to be given that the presence of deafness in a boy is produced by a blow or slap in the face in the region of the ear, unless an examination has been made immediately at, or about the time of, the occurrence. That is the view of all authorities upon the subject. I do not know Dr. Rounds. I have never met him before. Patients often come to me stating that they have had falls, etc., and date the deafness from that time, when changes had actually existed in the ear for a long time, and the deafness was due to pathological changes in the ear itself.

Those who read the cross-examination will notice the evil effects of the present system of securing expert testimony in leading the lawyers to attempt not so much to allow the expert to say what he really means as to make his testimony valueless by an apparent but not real contradiction.

Testimony of Dr. D. B. St. John Roosa, a witness sworn on behalf of the defendant.—I am one of the physicians of the Manhattan Eye and Ear Hospital. The divisions of the ear are the external, the middle, and the internal ear. The external ear commences with this portion (illustrating) and extends to the drum-head; the middle ear commences with the drum-head and communicates with the throat by the Eustachian tube, and on the other side is the nerve. The inner ear is where the auditory nerve is situated. The Eustachian tube passes into the middle ear from the throat immediately back of the tonsil. The Eustachian tube is lined with a mucous membrane. The nasal passages open directly into the Eustachian tube. The Eustachian tube ventilates the ear-chamber or tympanum so that the atmospheric pressure is the same on either side of the drum-membrane.

A blow over the ear would affect the hearing in two ways. It might produce a rupture of the drum-head, and it might not produce a rupture, but might produce a concussion of the nerve and of the brain.

Q. And of the inner ear?

A. Of the inner ear. That result is produced by the compression of a column of air in the auditory canal by direct violence upon the mouth of the ear. The blow must come so that the air in the canal will be compressed. In order to produce a compression of the air in the auditory canal, I should think that it would be necessary that the opening over the ear should be closed for the time being, either by direct violence upon it or by being pushed up and closed.

Rupture of the drum-head would perhaps be accompanied by concussion of the nerve, but we may have concussion of the nerve without a rupture of the drum-head. We tell whether or not the nerve has been affected by a blow by the use of a tuning-fork which is placed in vibration by striking it upon some object, and it is held in front of the ear for one test, and then it is put on the bone behind the ear for another test. If the tuning-fork be heard better through the air than through the bone, and there is at the same time impairment of hearing, that impairment, in my opinion, depends on disease of the nerve. But, if the bony conduction is better than the aërial conduction, it depends upon disease of the middle ear, in my opinion, and not upon disease of the inner ear. The usual symptoms of rupture of the drum-head from a blow are bleeding from the ear, and often there is a watery discharge if there be no bleeding; but usually there is bleeding, and generally sickness at the stomach,

inability to walk straight, and a complaint of dizziness. If there be a rupture of the drum-head, a discharge of blood is almost invariably present. A serious rupture might heal in two days, but it would show traces on examination. I should not consider a rupture serious where there was only a complaint of pain in the ear for a few days after the occurrence.

Q. In your opinion, from your experience as an aurist, would you say that a slap from the hand of a gentleman of about my size upon the cheek of a boy, given with such a degree of force only that the boy was not stirred from the perpendicular, could produce any impairment of hearing?

A. I should not.

By the Court.—Suppose it was sufficiently weighty to actually disturb him from the perpendicular and throw him against a person standing near; would that, in your opinion, be sufficient?

A. I think it might. The most frequent causes of deafness in children are colds in the head, commonly called naso-pharyngeal catarrh by doctors, measles, and scarlatina, which produce the same results upon the nose and throat as are produced by colds in the head. The drum, Eustachian tube, and the mastoid cells make up the middle ear. In the diseases I have mentioned the inflammation travels up the Eustachian tube to the drum-cavity. If a patient has an inflammation of the back part of the throat, by continuation it goes into the middle ear, and there is the same kind of inflammation there. That inflammation narrows the tube, prevents ventilation, and makes the chain of bones that conduct the sound to the nerve rigid instead of flexible. I omitted to say that the passages of the nose suffer in the same way, and the patient, as one of the symptoms, does not breathe freely through the nostrils, but through the mouth.

There is a well-marked condition of chronic catarrh called "mouth-breathing," which is an evidence of chronic catarrh, though it might occur in very acute cases.

If it is permanent, it means a chronic condition. Catarrh is inflammation of the mucous membrane, and, when affecting the nasal passages and Eustachian tubes, is apt to affect both ears. One of the results of this want of ventilation in the middle ear, and of this locking together of the chain of bones, is a dragging inward of the drum-head, called by doctors a sunken drum-head. If a patient hears better at some times than at others, that is an indication of chronic catarrh. If the disease has not got to a dead level, there are variations in hearing. On a damp day the patient does not hear so well as upon a dry day.

Deafness, when caused by catarrh, in a child frequently exists for a considerable period of time before it is first discovered. Politzer's inflation is a means of ventilating the drum of the ear through the Eustachian tube. The patient takes a little water in the mouth and holds it, and the doctor puts a tube in one nostril and closes the nostrils over the tube, and, on a signal, the patient swallows, and at the same time the doctor forces a column of air from this tube back into the drum of the ear through the Eustachian tube. When the patient is in the act of swallowing, the soft palate lies back against the throat so that the air must go in, as it can not go down. That is the invention called Politzer's inflation, from Professor Politzer, of Vienna. If the hearing improves after the use of Politzer's inflation, it indicates that it is a disease of the middle ear. It almost exclusively brings relief in cases of catarrhal deafness. It is my experience that there is frequently a mistake made in regard to the cause of a discharge from the ear in children. I have known patients to call a discharge of salt rheum from the ear a discharge of matter from the deeper parts. I have known them to suppose that an abundant supply of wax was a discharge. On the other hand, I have known them to suppose a discharge of matter from the ear was only a slight affair. Sea-bathing is frequently the cause of trouble in the ear. Continuous presence in the water, so that the body becomes chilled, is a very frequent source of catarrh—not a very fruitful source, considering the number of children who bathe; but a certain percentage of cases do result from prolonged bathing. Catarrhal deafness can not be produced by a blow. A blow upon one side of the face might produce a concussion of the nerve on the other side. I never saw such a case, but, if it did produce a concussion of the nerve, I should say there would be no other result coming from it.

Cross-examination.—*Q.* Are you acquainted with Mr. X.?

A. I am not.

Q. You would judge him to be a man of considerable muscular power, would you not?

A. He has been pointed out to me since I came in. I should think he had fair muscular power.

Q. Looking at him in that way, and judging of his muscular power, how much harm do you suppose a man of that kind, exerting his muscular power upon a little chap about that size (pointing to the plaintiff) by striking him on the ear, could do to the hearing?

A. If he struck him on the ear, I think he could do a great deal of harm.

Q. Do you think he could produce inflammation of the drum-head?

A. I think so.

Q. And inflammation of the drum-head leads to deafness, does it not?

A. It does.

Q. It is accompanied by deafness, is it not?

A. Inflammation of the drum-head is usually accompanied by deafness.

Q. Inflammation of the drum-head is distinguished from rupture of the drum-head. It is a different thing, is it not?

A. It is. We have inflammation without a rupture.

Q. But there can't be rupture without inflammation, can there?

A. Hardly.

Q. Inflammation of the drum-head is frequently followed by a discharge from the ear, is it not?

A. It is.

Q. And in a sense it may affect the hearing in both ears, may it not?

A. Not if I understand your question correctly.

Q. Inflammation, the result of a blow on one ear, may it not in some way affect the hearing in the other ear?

A. I think not.

Q. Not through a nerve?

A. Not through a nerve, if it is an inflammation of the drum-head.

Q. But a blow inflicted upon one ear may affect both ears, may it not?

A. I should judge that it might.

Q. Where a young child, five or six years old, is suffering from a nasal catarrh, which does not at the time affect his hearing at all, but a catarrh which is in the head, have you not known of a blow inflicted upon the ear to affect the hearing very materially?

A. I was just thinking. I know of the case of a boy who fell from his horse and hit his ear on one side and ruptured his drum-head, and had an inflammation of that side, but he did not have any of the other. I don't know of both ears being affected from a blow on one side.

Q. What I wanted to direct your attention to was this: Suppose a boy is suffering from a catarrh of the head, as a great many people suffer at certain seasons of the year, a young child,

and a severe blow is inflicted upon the ear, is he not more likely and liable to become deaf from that blow inflicted while he has this catarrh in the head than if he was in a healthy condition?

A. Certainly.

Q. It very frequently happens that a slight blow on the ear will create deafness?

A. I do not know that it does.

Q. The ear is more susceptible when there is catarrh in the head?

A. Yes; the drum of the ear, if there is catarrh in the head, is much more liable to be broken.

Q. You never examined this boy, did you?

A. No.

Q. Suppose a patient came to you, a little boy of whose hearing there had been no complaint until he had received a severe blow on one ear, and from that time on his hearing had been affected and he had inflammation of the drum-head, would you not attribute the inflammation to the blow?

A. I might. It would depend upon the history of the boy and other circumstances.

Q. I wish you would mention any other circumstances that would influence your judgment, or that would change your judgment, that the boy's deafness came from the blow.

A. If he was deaf on both sides, and he had a blow on one, I should conclude that he was probably not deaf from the blow.

Q. Suppose the boy's hearing had never been affected before that blow, and the blow had been a severe one, to what would you attribute his deafness?

A. I would go into the case. I should have to see the case. I could not isolate it in that way. It is a very common occurrence for us doctors to have a diagnosis made out for us beforehand.

Q. Would you attribute it to anything?

A. Not until I had examined the case for itself; I should not dare to.

Q. Suppose you found that the boy's hearing had been perfect before he received this blow, and then his hearing had been affected in both ears, would you not conclude that the blow had had something to do with it?

A. I should suspect it.

Q. You have consulted with Dr. Bacon, have you not?

A. I have consulted very freely with Dr. Bacon this morning or yesterday—I have forgotten exactly—within a short period.

Q. As to this case?

A. As to this case, and I heard as to what he found on an examination of the case.

Re-cross-examination.—*Q.* Don't you rely upon what you are told?

A. Very little in regard to medical cases. I regard what I see.

Q. You can't say how long before a man is brought to you he became deaf, can you?

A. No.

Q. Suppose you were told he became deaf at a certain time, don't you regard that as a circumstance?

A. I don't regard that as a fact because I am told it.

Q. You don't base any assumption upon that at all?

A. Very little.

Q. If this boy were brought to you and you were told that from the time this blow was struck his hearing was impaired, you would not place any stress on that?

A. I should place some stress; I should investigate, but I should not necessarily believe it.

Q. And you could tell whether that was so always?

A. No, I could not.

Re-direct Examination by defendant's counsel.—*Q.* Is it or is it not a fact, from your experience, that the large number of cases of rupture of the drum-head are actually cured?

A. I can't answer that directly. A rupture of the drum-head accompanied by concussion of the nerve may heal up easily and leave no scar; I have seen it, and yet the person remained deaf. Ruptures with concussion of the labyrinth, when the nerve is not injured, that heal up promptly, are slight affairs.

Re-cross-examination by plaintiff's lawyer.—*Q.* When they don't heal up for a couple of years they no longer become slight affairs?

A. They are pretty serious then.

Q. (by the Court). The physician who was on the stand a short time ago said that this boy, upon his examination, was suffering from a chronic catarrh—that seemed to be his diagnosis—and an opaque condition of the drum-head. Is an opaque condition necessarily an inflammation?

A. It is a result of inflammation.

Q. Would a catarrh follow such a blow or such an injury of the ear; would it be incidental at all?

A. Hardly.

Q. If you found catarrh existing, what would be your inference as a physician as to the causes of the deafness?

A. That the catarrh caused it.

Q. The catarrh, then, would not be superinduced by the blow, in your opinion?

A. I think I have already stated that I did not see how catarrh is induced by a blow.

Q. Then, as a matter of fact, if the catarrh was existing as a chronic condition, in your opinion, it would have some other cause than the blow?

A. Probably.

Q. Could you tell whether catarrh had existed for six or twelve months by examining the patient?

A. Not positively.

Q. It can become chronic in six?

A. I should call six months pretty near chronic.

Q. If you found catarrh accompanied by inflammation of the drum-head, and were told that the boy's hearing had been impaired from the time of receiving a severe blow, you would conclude, would you not, that the blow had something to do with the inflammation?

A. As I said before, not necessarily. I decline to answer that question that way because I can't. I should have to look into the circumstances. I do not see how catarrh can be caused by a blow. I have said that two or three times.

Q. We are talking of a case of catarrh accompanied by inflammation of the drum-head?

A. But catarrh is inflammation.

Q. But I am speaking of a local inflammation of the drum-head. You know that succeeds a blow?

A. I do not know such a thing as a local inflammation of the drum-head in conjunction with catarrh. I don't know how to make such a diagnosis.

Q. You could make a diagnosis of a local inflammation of the drum-head existing with catarrh in the head, could you not?

A. If there was a rupture of the drum-head I could make a diagnosis of rupture.

Q. Existing with catarrh?

A. Existing with catarrh of the head, certainly.

Q. And you could conceive of such a rupture succeeding a severe blow?

A. I could.

Q. You have been asked something about sea-bathing. Is it your experience that inflammation of the drum-head succeeds sea-bathing?

A. In some instances.

Q. And if a boy had been sea-bathing a great part of the summer, June, July, and part of August, and in August somebody struck him a severe blow on the ear, and inflammation of the drum-head followed immediately and continued, you would not ascribe it to sea-bathing, would you?

A. Not necessarily.

This case is perhaps an average exhibition of the uselessness of endeavoring to settle cases, which should be determined by experts, by referring them to an ordinary jury of laymen. The medical evidence is so technical that it is literally impossible to cause any jury made up of laymen, however intelligent, to render a verdict in accordance with the facts.

The plaintiff in the case now under discussion secured a verdict for $400. If this was intended as a compensation for an assault, it might perhaps be justified, for an assault of a mild character did occur.

As a compensation for loss of hearing, it is, of course, entirely inadequate. It is probable, therefore, that the jury was convinced that no damage to the ears resulted from the blow. This certainly was the opinion that both of the present writers entertained. Dr. Rounds, the witness for the plaintiff, said nothing in his testimony that could contradict this view. He simply testified that he treated the child, whom he saw for the first time long after the incident which caused the suit, for catarrh of the nose, pharynx, and of both middle ears. By far the greater weight of evidence went to show that the boy was struck on the cheek once, not sufficiently hard, however, to move him from a perpendicular position, and not on the ear; that he soon ate his dinner and appeared as usual. A blow upon the cheek, in order to hurt the ear, would have certainly moved the boy, and probably have knocked him down. It would also have caused dizziness and other symptoms than those complained of; a severe blow of this kind might press the column of air in the auditory canal upon the membrana tympani, and in a catarrhal subject rupture it, or, without rupturing it, produce a serious lesion of the labyrinth. Such an injury would usually be confined to one ear, at least for a long time.

It is not yet settled whether sympathetic otitis ever occurs. It is believed by one anatomist at least that the nuclei of origin of the acoustic nerves communicate directly with each other. In this case not only is there no evidence of any kind that the boy suffered from vertigo, nausea, or bleeding from the tympanum after the blow; but, on the contrary, the testimony of one well-known, respectable, and intelligent lay witness was that the boy did not hear well for some time before the blow.

It was also shown that he was at a sea-side resort, in the habit of bathing and diving and remaining in the water for long periods at a time; that at the time of the slap both parents were away, his father in Europe and his mother away on a week's visit, and the boy was left in the sole charge of the colored nurse, who was the principal witness for the plaintiff as to the nature of the blow. When he was examined by a general physician he found an abscess of one ear (he did not remember which). This was some two months after the blow. It is understood that the boy remained several weeks longer at the sea-side in the mean time, and that he continued his usual habits there. This physician did not profess to be an expert in aural diseases, and it was not shown through him where the pus came from, or indeed anything that would enable us to know whether the abscess of the ear was situated in the canal or tympanum, or that it resulted from the blow.

When he came under Dr. Rounds's care in April, 1884, six months afterward, the boy had chronic catarrh of both middle ears as well as chronic naso-pharyngeal catarrh, and Dr. Rounds found the ear on the opposite side of the head from the one upon which the blow was inflicted the worse. He thought the trouble had existed for a long time.

When examined by Dr. Bacon, the case was a typical one of chronic aural catarrh. When first seen, the child was hearing quite well, but, on the second visit, he was suffering from a subacute attack, such as is common in young subjects who have chronic catarrh.

In the light of this evidence, it seemed preposterous to Dr. Roosa, who was called as an expert, to assume that the blow had anything to do necessarily with the causation of the disease. Certainly, blows on the head, however severe, do not cause naso-pharyngeal catarrh, and, while an affection of the ear may be produced by a blow, such a disease would be entirely different in character from that shown by the testimony to exist in this boy's ears.

One of the counsel for the plaintiff, in cross-examining Dr. Roosa, was very much surprised to find that the latter laid so little stress upon the history as given by the patient's friends, and their conclusions as to the cause of the disease.

Over and over again he inquired, "If a patient were brought to you who stated, or whose friends stated, that he or she heard *perfectly well* until after a blow was received upon the ear, would you not believe that the deafness was caused by the blow?" When Dr. Roosa replied "Not necessarily," the lawyer showed by his surprise that he did not understand how unreliable such testimony as this was, even when honestly given and with no intent to deceive.

In this case, the testimony that the boy heard perfectly well just before the blow was contradicted, and the colored nurse, who was left in charge of the boy, was the only witness who testified to the perfect hearing *just previous* to the accident. His father, being in Europe, had not seen him for several weeks, and his mother was away on a week's visit and did not see him several days before the alleged assault. But it is quite possible that the boy generally heard very well until his season of bathing at the sea-side. It is impossible to get over the testimony given by one of our most reputable citizens, who was in daily contact with the boy, that he did not hear well just before the blow was received (that is, during the previous part of the summer), and that his habits of bathing, etc., were such as to lead to just such a disease as the medical testimony on both sides, to a greater or less extent, united in showing that he had.

Nothing is more unreliable and misleading, if trusted, than the testimony of patients and patients' friends as to the causation of disease. The lawyer, as well as the physi-

cian, knows that even the facts, and an interested person's account of them, are sometimes entirely at variance. When it comes to deductions drawn from facts, the non-expert mind will inevitably fall into error. We are very often obliged as physicians to give very little credence to the history of cases, but lawyers often seem as credulous as laymen in regard to theories of the causation of disease, and the value of testimony upon which these theories are based.

Fortunately, in the examination of the ear, we have in the speculum, the otoscope, and the tuning-fork aids to diagnosis which enable us to look at cases with considerable objectiveness. If a patient comes to us with the statement that, while hearing well, he received a blow on the ear which caused tinnitus, pain, and perhaps vertigo, that he soon found his hearing defective in that ear, and that it was growing worse, if we examined the drum-head and found no lesions, and yet the patient's hearing was impaired on that side, and the tuning-fork was heard better through the air than through the bones, we should conclude that the history was correct and that he was suffering from concussion of the nerve or labyrinth, the result of a blow. But when a disease is found that is not at all likely to have resulted from a blow, certainly we would not *necessarily* conclude that it had so proceeded, no matter how strongly his friends might insist upon it. Expert testimony as now given by physicians chosen by the counsel, and not by the Court, and before a jury of laymen, is often of no value, and sometimes brings the medical profession into disrepute, and, what is worse, defeats the ends of justice. Medico-legal cases should be settled by juries of medical men, and experts should be witnesses called and paid for by the Court.

DEFORMITIES OF THE NOSE
AS A FACTOR IN NASAL CATARRH.*

By J. W. ROBERTSON, M. D.,
DETROIT.

Every physician who has paid any attention to diseases of the nose has noticed that a large proportion of the applicants for his professional services have some deformity of the nasal organ, varying from a slight deviation of the septum to a complete obstruction of one or both nostrils.

Many noses which to all external appearances are perfectly straight are often found, when examined internally by the aid of a nasal speculum or rhinoscope, to be deformed to an extraordinary extent, and in a large majority of these cases the patients suffer from the various forms of catarrh.

Now, it becomes us as specialists to give to the general medical profession the results of our researches into the causes of these deformities and their relation to the catarrhal diseases of the nose and throat.

With this object in view I have been investigating some of the causes of the so-called catarrhal inflammations, and have come to the conclusion that deformities of the nose stand at the head of the list.

* Read before the American Laryngological Association, June 25, 1885.

But we must needs go further back than the mere fact that deformities exist. Immediately many questions arise.

1. What are the causes of the large number of deformed noses?

2. At what age do these deviations from the normal take place?

3. In what way do these deformities produce catarrhal diseases?

4. How can these abnormal conditions be prevented?

It will not be the province of this paper to discuss all the various questions that may arise in this connection, or go into any extended debate in regard to them, but simply to give the observations made and the deductions therefrom.

1. Causes of deformities.

Of one hundred and sixty patients (males) examined, thirty-seven gave histories of injuries received before the age of twenty years; nineteen others were injured after attaining that age, having fractures, dislocations, etc., due to external violence. Sixteen deformed noses were the results of tertiary syphilitic manifestations.

Twelve cases of congenital deformities were consequent upon improper development in hereditary syphilis, scrofula, etc. Three perforations of the septum resulted from necrosis during typhoid fever. One case of necrosis of the vomer and turbinated bones followed injury and long-standing suppuration of the lower extremities. One case of perforation of the septum followed vaccination in a tubercular subject, afterward culminating in general tuberculosis and death. Two cases of perforation of the cartilaginous septum resulted from ulceration due to injury of the mucous membrane by the finger-nail. One case of congenital occlusion of one nostril was caused by attachment of the posterior portion of the vomer to the inferior turbinated bone. The remaining cases gave no histories of injuries having been received; quite a number had high-arched, irregular palates, which were undoubtedly congenital, and nearly all were suffering more or less from catarrhal difficulties.

Of fifty-seven patients (females) examined, five had had recent fractures, the results of blows, falls, etc., upon the nose. Twenty-two gave histories of injuries from violence. Eleven cases were due to tertiary syphilis and congenital non-development. Two were cases of lupus. Three were cases of asymmetry of nasal cavities, probably congenital; partial obstruction to one nostril since early childhood; no histories of injuries. The causes of the deformities were not known in the remaining cases, but nearly all the patients were troubled with the various catarrhal diseases.

Of two hundred and forty persons of both sexes examined, two hundred and seventeen had deformities of the nose. Of the two hundred and seventeen, eighty-three gave histories of injuries received; and, of the ninety-seven remaining, having no histories, in all probability one half of them had had injuries early in life and had forgotten them, because many of them had dislocations of the cartilages and fractures of the nasal bones, which could only have been the results of external violence. It would appear from the foregoing that a large percentage of the deformed noses were directly due to injuries received—syphilis, scrofula, tuberculosis, and allied diseases, causing necrosis, ulceration,

and congenital improper development, coming in a good second in the production of these abnormal conditions.

2. At what ages do these deviations from the normal take place?

Through the kindness of Dr. E. A. Chapoton, I was enabled to examine at St. Vincent's Orphan Asylum and the Home of the Friendless two hundred and thirty-three children, ranging from two to eighteen years of age, the object being to determine, if possible, at what age these deformities began to be made manifest. I have tabulated the following:

Ages.	No. examined.	Normal	Abnormal.	Deformed.	Syphilitic, Scrofulous, Imp. Dev.	DEFORMED NOSES.	
						Histories of injuries	No histories of inj.
2 to 5	46	36	10	1	5	1	..
5 to 10	115	91	24	6	9	3	3
10 to 15	64	35	29	20	9	5	15
15 to 20	8	5	3	2	..	1	1

From the foregoing it will be seen that in a total of one hundred and sixty-one children, at ages ranging from two to ten years, only seven deformities existed, and four of them gave histories of injuries. In a total of seventy-two children, between the ages of ten and twenty years, there were twenty-two deformed noses; six gave histories of injuries, while in sixteen the causes were unknown, although five had dislocation of the septum and one had disarticulation and depression of the nasal bones; four had narrow superior maxillary bones, high-arched palates, crowded teeth, and deviation of the nasal septum. Quite a number gave histories or indications of syphilis, scrofula, or tuberculosis. In a total of thirty-two children under ten years of age examined in private practice, only one had any deformity of the nose. It would appear from this that between the ages of ten and twenty years a large proportion of the deformities manifest themselves either through the receipt of injuries or improper development due to malnutrition.

3. In what manner do these deformities produce catarrhal diseases?

Nearly every person is subject, more or less, to frequent attacks of coryza, influenza, etc. Ordinarily these attacks last only a few days, and the patient eventually recovers with no untoward symptoms; but, when these diseases occur in persons afflicted with any of the numerous deformities of the nasal organ, there will always be some interference with the proper drainage therefrom.

The secretions accumulate to a certain extent in some portion of the nasal tract, thereby causing an irritation by drying or undergoing decomposition. This irritation is kept up for a greater length of time in these cases than where no abnormal conditions exist; a subacute catarrhal inflammation supervenes, leaving the patient liable to subsequent attacks of coryza with increased irritation, repeating itself until eventually a chronic inflammation, with its concomitant symptoms, results. In the same way individuals having deformed noses, who are obliged constantly to breathe air impregnated with irritating substances, are liable to have chronic inflammations of the nasal mucous membrane, on account of an inability to dislodge the irritating particles because of the abnormal projections and cavities.

Again, in those unfortunate children who have inherited syphilitic and scrofulous diseases, where there is an interference with the proper nutrition of the entire system, there seems to be particularly a condition of malnutrition of the nose and throat, usually a lack of proper bony growth, the nasal bones being short and small, the vomer resting upon a flat palate, the bridge of the nose slightly sunken and broad, the point tilted up, the nostrils large and open, allowing in many cases too free a circulation through them, which has a tendency to dry and harden the secretion in the nose and upon the membrane of the pharynx, producing ultimately ozæna, pharyngitis atrophica, or diseases of a severer character of the upper air-passages and lungs. These children usually exhibit a tendency from birth to chronic discharges from the nose, and eczematous eruptions of the lips and nostrils, the nasal passages being deformed and allowing too much air to pass through them, as stated above, causing the secretions to dry upon the surface of the mucous membrane, producing considerable pressure and atrophy of the underlying tissues. In this way many of the cases of atrophic catarrh may be accounted for.

4. How can these abnormal conditions be prevented?

It devolves upon the medical profession to instruct the people that the time to prevent catarrh and its concomitant diseases is during the growing period of childhood.

We can not prevent children from falling down stairs or boys from playing ball and fighting, but the resulting deformities can be, to a certain extent, relieved; for during early life the cartilages and bones can be more easily molded into shape, and fractures and dislocations more easily reduced, and they should be looked after with as much care as fractures and dislocations of the arms and legs. The nose should have at least as much care as the teeth, for it is far more essential to health, and, should its functions be impaired or destroyed, no false one can replace it.

In those cases of syphilitic and scrofulous diseases where the secretions are profuse and inclined to adhere to the mucous membrane, it is usually necessary to cleanse the nostrils constantly with some bland fluid, and apply oil by means of a spray, which will prevent, to some extent, the constant irritation. In children the utmost care must be had in regard to the hygienic surroundings, and an attempt made, by proper treatment and feeding, to develop, if possible, the bony structures of the nose.

DISCUSSION.

Dr. Mackenzie referred to the custom of the ancient Persians with reference to securing symmetry of the nasal chambers in the children of the royal blood. No man was allowed to sit upon the throne who had a crooked or deformed nose, and the eunuchs who had charge of the royal offspring were accustomed to mold their noses into perfect shape. Cyrus, it is said, had an asymmetrical nose, which was made a thing of beauty through the kind interference of his emasculated attendants. In regard to the undue arching of the palatine vault, first advanced by Duplay and subsequently elaborated by Jarvis, Dr. Mackenzie was inclined to regard it as an inconstant ætiological factor, although he fully recognized the importance of asymmetrical conditions of the nasal fossæ as factors in the production of septal deflection.

A CASE OF CÆSAREAN SECTION, AND ONE OF EXTRA-UTERINE GESTATION.*

By ROBERT ABERDEIN, M. D.,
SYRACUSE, N. Y.

Mr. President and Fellow-Members: I venture to present to you this morning the histories of two cases which occurred in my practice, their rarity and my irregular attendance at our quarterly meetings being my only excuse for bringing them before you at this late day.

A CASE OF CÆSAREAN SECTION.

On the evening of the 16th of June, 1881, I was notified by Mr. S. that his wife was beginning to have labor pains with her first child. Accordingly, I called about 10 P. M.; found her reclining on a sofa awaiting my arrival. She said she was feeling pretty easy, and, thinking she might rest for the night, I made no examination, but left her, promising not to accept any other call that night. About 2 A. M. of the 17th the husband came for me again. On my arriving at the house, the nurse informed me that the waters had broken. I made an examination and found what I considered to be the head well down in the middle strait, but could not detect the os. After a while I made a second examination, first giving a few whiffs of chloroform, when I introduced my hand far enough up anteriorly to distinguish the os not much dilated. The pains not being very strong, I did not examine again for some time. At the third examination, by bimanual taxis I found a tumor above the pubes, and through the os detected the fontanelle. Then I knew I had a formidable case to deal with, and requested counsel. Dr. A. Mercer was sent for. He, too, thought he felt the head, but could not find the os until, under chloroform, he searched for it as I had done. I had previously tried to force up the tumor into the abdominal cavity, thinking that by dislodging it I might turn, should the head not engage.

I now applied the forceps and endeavored to press the head back, while Dr. Mercer tried to push the tumor up out of the basin of the pelvis. After successive efforts and failures we asked for another physician, and Dr. Van de Warker was sent for. When we had told him our experience, he, after examining, said, "Why not aspirate?" We attempted to, but did not succeed in getting a drop of fluid. Then one of us proposed the Cæsarean operation; it was conceded by the others to be the only resource left; the family were informed, and a ready consent was given. Leaving Dr. Mercer and Dr. Van de Warker with the patient, I started out to get the instruments required and invite a few medical friends to assist. About noon, the patient being anæsthetized, Dr. Pease, Dr. Van Duyn, Dr. A. C. Mercer, Dr. Cook, Dr. Stephenson, and Dr. Slocum were admitted to the room. The woman was placed upon the operating-table and Dr. Pease made the examination for the other physicians. His opinion coinciding with our own, and all deciding the Cæsarean section to be the only possible procedure, I performed the operation, assisted by a sufficient number of my colleagues, delivering the mother of a finely developed, healthy daughter. The placenta was removed through the wound, and so skillfully had my friends applied the pressure that not a drop of fluid escaped into the abdomen. The uterine incision was brought together by interrupted sutures of carbolized catgut.

Before the abdominal wound was closed it was asked whether it was better to remove the tumor. On examination, several thought the pedicle to be too short and thick, and, wishing to give the patient every chance, it was left *in situ*. The woman rallied nicely from the chloroform, and I stayed with her for the succeeding eighteen hours, during which time she complained very little of pain, took what was given her, caressed her baby, and often asked why I would not allow her to turn and twist in bed as she wanted to. The urine was drawn off every fifth or sixth hour, the vagina at the same time being examined and the lochial discharge noted to be nearly normal in quantity and quality. On leaving the house I cautioned the nurse not to allow any one to enter the room during my absence except the husband. I had not been gone long, however, when some of her friends visited her, and one, more officious than the rest, told her she had been cut open and the baby removed in that way. This was the first intimation she had of the operation; the news, and the graphic way in which it was communicated, produced a shock; she fainted, rallying partially after a while, only to pass into another faint more profound, and about twenty-five hours after the operation she quietly passed away. Dr. Mercer, whom I found with her when I returned, had done all that was possible to revive her, and coincided with me in attributing the direct cause of death to delayed shock.

At the autopsy, performed twenty-four hours after death by Dr. Jacobson and Dr. Elsner, Dr. Mercer, Dr. Pease, and myself being present, the following notes were made: Subject, a well-developed blonde, five feet three inches in height, about one hundred and thirty pounds in weight, twenty-nine and a half years old. On reopening the abdominal wound, no signs were found of commencing peritonitis; the uterus and its appendages were removed; the abdominal cavity contained very little if any fluid. The tumor was found to be egg-shaped, attached, by a round pedicle three fourths of an inch long and one inch in diameter, to the posterior wall of the uterus five inches from the os, the entire length of the womb being nine inches. The natural position of the tumor had been transverse, as was shown by the position of the fibers of the pedicle; but its attachment, being a little nearer the smaller end, had allowed the heavier extremity to dip down into Douglas's *cul-de-sac*. The dimensions of the tumor were: long circumference fourteen inches, long diameter six inches; circumference of large extremity twelve inches, diameter four inches.

On a section being made into it, the walls were found to be over an inch thick, very hard and unyielding. The interior resembled that of a kidney.

After having completed the post-mortem and closed the cavity, it was found that in some mysterious way we had neglected to return the specimen. Not knowing how better to dispose of it, it was handed over to Dr. A. Clifford Mercer, who promised to prepare it for the histological museum of the Syracuse University; hence I am enabled to present it for inspection now.

I met Mr. S. only a few days ago, and he informed me that the little girl was growing nicely and had seldom seen a sick day.

CASE OF EXTRA-UTERINE GESTATION.

On April 24, 1884, I received a note from Mr. M., asking when it would be convenient for me to visit his wife. I answered at 5 P. M., about which time I called, and was met by the family physician, who gave me the following brief history of the case I was called to see: Mrs. M. had given birth to a vigorous, healthy boy about eight years before, since which time she had never been pregnant. In January he was called to her, and,

* Read before the Medical Society of the County of Onondaga.

the symptoms indicating suppression of the menses from cold, he gave her some remedies which restored them, but she had not menstruated since. For the past two weeks she had been confined to her bed, suffering from a pain in the left side of the abdomen, had considerable nausea, and the bowels were constipated. He was at a loss to know whether these symptoms were from pregnancy or some other cause. On entering the sick-room I found the patient in bed; her countenance was pale, and had a worn, anxious expression; the skin appeared to be normal in temperature; pulse rather rapid. After a brief interview I made a digital examination. I found the womb enlarged, the os having that peculiar, indescribable feeling attendant upon gestation. The breasts, too, had commenced to enlarge, and the areolæ were darker than normal. I did not hesitate to pronounce her pregnant and about in the third month. On examining the abdomen, I found considerable tenderness on the left side. She said she felt easier when the left leg was flexed. She had had chills, and nausea was very persistent. I advised citrate of magnesium as an aperient and stomachic sedative, and the abdomen to be painted with ol. menthæ pip., then covered with a heated flannel, over which an abdominal bandage was to be firmly applied. She seemed much relieved and greatly pleased when I expressed my belief in her being pregnant. On May 13th the husband called to say that his wife was feeling much better, but would like to have me call again, as she wanted to know if I was certain she was *enceinte*. On a second examination I reiterated my former statement, as I was able to detect the uterine souffle in the left inguinal region. She had improved very much since my first visit, and was up and about the house. I advised her to take as much out-of-door exercise as she could without fatiguing herself, and live on plain, substantial food. In the course of a few weeks the husband called and jubilantly informed me that his wife had felt life a short time before, and that she had improved very much since. From this time on I heard nothing of the case till September 18th, when I was called in the evening, and found the family physician there. He said pains had commenced two days before, and he had remained with her both nights; as she was pretty well worn out, he requested me to make an examination and determine whether labor had actually commenced. On doing so, I found the parts relaxed and pretty well bathed in that albuminous mucus which lubricates the vagina during parturition. The mouth of the womb was soft and dilatable, but no part of the child was presenting. The nurse said the movements of the fœtus had been so strong a few days before as to kick a book off the mother's lap as she lay reading. I told them labor was commencing, but, as there was no presentation at present, they would have ample time to summon the doctor when he was needed, and advised an anodyne to procure rest. Some time after this I met the husband on the street. He said he was very anxious about his wife, as she had not been confined yet, and had not felt life since I last saw her.

On November 27th he called and asked me to take charge of the case. On doing so I explained to them the necessity of determining whether the fœtus was in the womb or abdominal cavity, as I had grave fears that something was radically wrong.

The patient was able to retain but very little in the stomach; fever was pretty constant, although she had no chills, and there was circumscribed soreness on left side of the abdomen, which was distended as at full term, and tympanitic. I could not detect the fœtal heart-sounds nor determine the location of the head. The following evening I called upon Dr. Didama, who went with me and administered ether while I dilated the womb and explored it, only to find it, as I had feared, empty. The doctor verified my statement, and I, knowing what I did, was certain there was a dead fœtus in the abdominal cavity; but the patient was in such a prostrated condition that we concluded to wait, endeavoring to build up her strength and trust to either mummification or the establishment of a fistulous opening into the vagina or rectum, as sometimes does occur. Various remedies were tried for the persistent nausea, which would succeed one day only to fail the next. Opium in any form gave no relief, but rather increased the intolerance of the stomach. Dr. Van de Warker saw her with me, and advised an enema of ʒj each of pot. bromidi and chlo. hydrat. at bedtime; total abstinence from anything by the mouth for twenty-four hours. This did not act kindly, and, after three trials, I abandoned it, again trying morphine hypodermically, which, with ten-grain doses of oxalate of cerium occasionally, gave most satisfaction. To nourish her, an enema consisting of one egg, half a tablespoonful of cod-liver oil, one grain of quinine, a teaspoonful of brandy, and milk enough to make about three ounces, was given every fourth or fifth hour. She now seemed to improve, and, as there were no symptoms of septic poisoning, we began to hope that, after all, she might get better. On the morning of December 15th, on entering the house, I discovered a most horrible odor; passing into the sick-room, the nurse informed me that in the middle of the night something seemed to break, and there was a gush of fluid from the vagina. On separating the legs, the discharge came with a force and sound resembling escaping steam, saturating everything on the bed and almost filling a bedpan, which she hastily placed in position. The patient lay passive and faint. I gave her some brandy, and, on applying my hand to the abdomen, found the distension very much reduced. I discovered, on examining *per vaginam*, that the fluid came through the mouth of the womb, so concluded that the passage was either through the left Fallopian tube or uterine wall. The fluid was of a dirty grayish color, interspersed with spots of pink. Pouring it carefully from the vessel, I succeeded in getting a small shred of membrane which, under the microscope, proved to be skin, with a few delicate hairs *in situ*. I thought we should probably have septicæmia following rapidly, and that a few days at most would end the patient sufferer's time on earth. But, instead of our forebodings being fulfilled, she rallied more than before. Day by day the discharge kept up, the patient gradually improving, and finally the nutrient enemata were nearly altogether supplemented by nourishment *per os*. The husband, whose business had long required him elsewhere for a time, now, on my suggestion, left, but three or four days after was telegraphed for, as grave symptoms had appeared. On the morning of January 3d I found that, during the night, the discharge had suddenly ceased, and the abdomen was again distended as much as before. I endeavored, by introducing a large gum-elastic catheter into the uterus, to find the opening, which had become clogged, but did not succeed. The patient lost strength rapidly; chills, delirium, and other septic symptoms set in; toward the last she became comatose, and, on January 7th, during the night, her troubles ceased.

I was notified of her death early in the morning of the 8th, and, as she had requested a post-mortem examination in the event of her death, was urged to make it as soon as possible.

I called upon three physicians who had seen the case; one was out, the two others were engaged. Dr. Ensign, of Oxford, N. Y., who was visiting in the city, and had called with me a week or so before, was next waited on and gladly consented to be present. Mrs. Dr. Dann, hearing of the autopsy, came in. On opening the abdominal cavity, we first encountered a rather dense membrane, which, on being cut into, disclosed a full-term fœtus in an advanced stage of decomposition. This was carefully removed, when a round opening about three eighths of an inch in diameter was disclosed, communicating with the uterus through

the left wall, which was agglutinated to the sac very firmly. The two together were of about the thickness of a piece of chamois leather. In the posterior side of the sac was a rent about three inches long, leading into the abdominal cavity, where quite a quantity of the previously described fluid was found.

The mass of the placenta had been entirely dissolved, leaving only the vessels, like cords, clinging to the top of the sac, which was adherent to the flexure of the transverse and descending colon; the anterior surface was pretty firmly attached to the peritonæum of the left side. We determined that the sac was formed from the left Fallopian tube.

This, gentlemen, I present as the history of a case from which many valuable lessons are to be learned:

1. The unmistakable signs of gestation in the empty womb in tubal pregnancy, especially the entire absence of the menses.

2. The sympathy of the mammæ, as in normal pregnancy.

3. And, most remarkable, the preparation of that empty womb for parturition at the completion of gestation, and the part played in the same rôle by the vagina.

4. The resistance of the interior of the womb to the septic matters pouring through it for weeks.

5. The entire absence of septic symptoms until the sac ruptured into the abdominal cavity.

A REMARKABLE CASE OF LATENT PNEUMONIA.

By FRANK GRAUER, M. D.,

ASSISTANT TO THE CHAIR OF PATHOLOGICAL ANATOMY AT BELLEVUE HOSPITAL MEDICAL COLLEGE.

It occasionally falls to the lot of medical men attending hospitals and dispensaries to see cases of latent pneumonia, which assume various forms and symptoms, and may, as a rule, be classified under one of the following heads or types:

1. The so-called walking cases of pneumonia, in which there is partial or complete solidification of one or more lobes of a lung, with a few or all of the following symptoms: weakness, loss of appetite, fever, increased frequency of pulse, etc.

2. Those cases in which the symptoms of pneumonia are masked by the symptoms of some other disease, with which it is complicated.

3. Senile pneumonia, which in a large proportion of cases runs a latent course.

These cases, especially the second and third type, are, as I have stated, not infrequently met with in practice, but it is a comparatively rare thing to see a case of pneumonia with three lobes involved—one in the state of red, the other two in the state of gray, hepatization—which does not present any symptoms whatsoever indicative of or pointing toward the disease.

The following is a complete and correct history of a case in which the writer performed the autopsy.*

Mr. H., a German, aged fifty, occupation mason, was steadily employed until October 11th. The following day, Sunday, October 12th, he went to an entertainment at a friend's house, where he enjoyed himself, felt in the best of spirits, and sang three or four songs. On Monday, October 13th, not having any work to attend to, he went out walking, returned home in the evening, ate a hearty supper, and shortly afterward retired. When he awoke on Tuesday morning he felt that his throat was sore and that he was slightly hoarse. His daughter noticed that he was very pale, and, as she states, told him to send for a physician, but he was opposed to it, stating that he was feeling well and that he did not require the services of a doctor. He was very anxious to go out, but, the weather being unfavorable on account of the rain, he was compelled to remain at home. His daughter in the afternoon insisted that he was not well, and that he had better go to bed, which he did at 4 P. M., having previously washed his hands and face at the hydrant in the hallway. He slept until 6 P. M., when he awoke and arose to get his supper, but only drank some coffee, which he thought made his throat feel better. When asked later on how he felt, he remarked that he was not sick, that he had no pain, and that nothing ailed him. At 8.30 P. M. his next-door neighbor called to see him, told him he was looking very pale, and advised him to go and see the doctor, so as to satisfy his family. He promised he would do so, but remarked that he knew the doctor would tell him that nothing was the matter with him. At about 9 P. M. he had a cough for the first time, coughing three or four times in succession. At 10 P. M. he arose from his bed, walked to the door of his bedroom, a distance of about three feet, where he stood. His daughter asked him if he wished a drink of water, and he replied No, whereupon he began to shake from head to foot. I questioned the daughter as to whether it was a chill or convulsion, and she seemed inclined to think it was the former. After the chill, which lasted about a minute, he began to bend over as if about to fall, but was supported by his daughter and assisted to a chair, and thence to the bed, where he expired fifteen minutes afterward. The autopsy revealed the following points: An incision was made from the chin to the symphysis pubis, the integument divided, and an examination of the abdominal cavity made. The intestines were somewhat dilated and slightly congested, but showed no evidence of inflammation. The arch of the diaphragm was between the sixth and seventh ribs.

The sternum was then removed, and the lungs were found somewhat distended, covering the pericardium to a great extent. There were adhesions on the left side due to an old pleurisy, but none on the right side.

The pericardial sac contained at least three tablespoonfuls of a clear, reddish fluid. The heart was somewhat enlarged and the left ventricle contracted. There was also considerable hypertrophy of the left ventricle, the walls being of about twice the normal thickness. The aortic valves were slightly thickened at their bases, but the aorta was found normal.

The left auricle was dilated, and there was slight thickening of the mitral valves. The right ventricle was also dilated and contained a post-mortem clot, reddish in color and slightly adherent to the walls of the ventricle. The pulmonary valves were normal. There was a clot in the right auricle, dark red in color, and prolonged into the branches of the pulmonary artery. There was nothing abnormal about the tricuspid valves. The left lung was removed and the lower lobe was found to be covered with a recent fibrinous exudation. On making an incision into it, it was found completely solidified and in the state of gray hepatization. The right lung, at its lower portion, also had spots of recent fibrinous exudation, and, on cutting through the lung, the middle lobe was found in the state of red, the lower in a state of gray, hepatization. A portion of the exudation from the middle lobe was taken and pressed between two cover-glasses; in this way about a dozen specimens were made and examined by both Ehrlich's and Grammes's method of staining

* I beg to express my thanks to Deputy Coroner Dr. Jenkins, through whose kindness I obtained the autopsy.

for detecting pneumococci, a large number of which were found present. A microscopical examination of a portion of the lower lobe showed the air-cells filled with fibrillated fibrin, with a large number of pus-cells, granular matter, a few fat-cells, and occasionally a red blood-globule in its meshes.

The trachea, larynx, and œsophagus were apparently normal.

The spleen was of normal size, but very hard.

The kidney was enveloped in a mass of fat, the capsule was readily stripped off, and, on cutting into its substance, showed a slight amount of parenchymatous nephritis.

The bladder was slightly distended with urine, but showed no evidence of cystitis.

The stomach was pigmented, covered with mucus on its inner surface, and showed evidence of a chronic catarrh.

Intestines and pancreas were normal.

The liver was enlarged, and showed parenchymatous, and in some spots the beginning of fatty, degeneration.

The cause of death was undoubtedly paralysis of the right side of the heart, as the upper lobes of both lungs did not show any evidence of pulmonary œdema. In concluding, I would like to state that this case teaches us two things:

1. That the tolerance of pneumonia is variable in different persons. Here was a man with organic disease of the heart and three lobes of his lungs completely solidified, who yet did not complain of dyspnœa or shortness of breath, showing that the two upper lobes were sufficient to do the work of respiration.

2. That we should never rely on the remarks of a patient and direct our attention only to the part that he thinks is affected, but examine every organ carefully and thoroughly, so as to do justice not only to ourselves, but to all who are interested in the case.

ANGIOMA BENEATH THE TONGUE.

By W. H. HAYNES, M. D.,
NEW YORK.

Some time ago Mrs. F. was delivered of a well-developed female child, which was noticed to have a nævus on the lower lip at about the middle third, involving the mucous membrane and skin beyond the vermilion border to an equal extent of about three eighths of an inch. There was nothing noticeable within the mouth at this time. Three months later the child was brought to me on account of there having appeared beneath the tongue, on each side of the frænum, a smooth, glossy, globular swelling, looking exactly like the illustrations shown in text-books of typical ranula, except that in this instance there were two tumors. The one on the left side was much the larger, and both together were of such a size as to elevate the tongue and impede nursing and respiration, causing the latter to be distinctly nasal. They were bluish in color, soft, and fluctuating. The nævus had also increased in size, had become more prominent, of a bright red color, and frequently bled freely. Puncturing the tumor on the left side gave exit to a quantity of blue venous blood. A ligature was passed through the tumor after the manner of introducing a seton and tied tightly. This procedure was followed by a venous hæmorrhage (which after a while ceased spontaneously) and subsidence of the swelling. In a few days the tissue included by the ligature sloughed, became disintegrated, freeing the ligature and allowing the exit of a dark brown, spongy mass. This gradually melted away and union of the divided tissues took place, so that all that remained of the tumor was a small stump of connective tissue covered by mucous membrane. The same procedure was repeated on the right side. This time, however, the hæmorrhage consisted of bright red arterial blood, which ceased spontaneously as before. In all other respects the process of repair was the same as after the first operation. No further difficulty has been experienced in performing any of the functions of the mouth. The nævus, though growing *pari passu* with the normal development of the parts, oozes bright-red blood at times, which is checked by the use of styptics. Areas of cicatricial tissue have appeared in these places, so that we are in hopes that in time a cure of this deformity may take place by this process.

The pathology of this form of tumor consists in an over-development and dilatation of the capillary blood-vessels of a part, covered by the different tissues, according to the depth and place of location, in the present instance being covered by the connective tissue and mucous membrane lining the cavity of the mouth. They are always congenital. Their cause is unknown. Their occurrence upon the surface of the body is very common. In the different cavities of the body their development is rare; particularly is this the case with the cavity of the mouth, and it is still rarer for the deformity to be double.

There are two other forms of tumor—which are apt to be met with more frequently in this locality at this early time of life—with which these tumors may be confounded, viz., true ranula and cysts * (false ranula,† so called).

Dermoid cysts may possibly be located here also, but they have distinguishing features of their own for purposes of diagnosis. Labbe mentions having met with sanguineous cysts in this region, but, from his description, I believe them to have been analogous to those described at the head of this paper, of the same pathology, and not of that he mentions.

The three first-mentioned forms of tumor resemble each other so closely in appearance and feel during their development that our only certain means of diagnosis is by exploratory puncture, which can not possibly do harm, and may also bring about immediate cure. After such a puncture, if the tumor be a true ranula (simple closure of the mouth of the duct), the sac collapses with the exit of the clear fluid, and a probe can be passed along the cavity, remaining for a varying distance of about an inch till it reaches the gland structure. In the case of a false ranula (simple cystic tumors of the connective tissue), after the puncture the cyst partially collapses with the exit of the clear fluid, and the probe enters only a small limited cavity, which, being laid open, reveals the wall or walls of other similar cysts.‡ If, after the puncture, blood exudes, we know we have a tumor made up of capillary blood-vessels.

I have mentioned the contents of these tumors as being a clear fluid; but, to continue their natural history: "In older children the contents of these cystic tumors may be of dense consistence, like soft putty, which does not exude, but will have to be scraped out and the cyst-wall enucleated. This condition is due to the absorption of the watery part of the elements and consequent condensation of the organic material forming in true ranula a calculus, and in

* Cornil and Ranvier, Amer. ed., 1880, p. 453.

† Holmes's "System of Surgery," Amer. ed., vol. ii, p. 270.

‡ Holmes, *op. cit.*, p. 522.

false ranula an encysted tumor." * The angiomatous form of tumor may at this period contain a phlebolite.†

In the case under observation my suspicions as to the nature of the tumors were aroused by their occurrence in the immediate vicinity of a nævus, leading me to suspect a similar condition to be the cause of their appearance, which the puncture confirmed. This, however, would naturally be so in any case where the two conditions were met with, no matter how remote they were located from each other. Another point of interest and aid in diagnosis was the different colors of the blood exuded from the two tumors, showing them to be of a vascular character, in the one the veins predominating, and in the other the arterioles.

The treatment and cure of this variety of morbid growth is of the simplest kind, and consists in merely passing one or more ligatures through the growth or around its base, tying it tightly, and causing sloughing and subsequent cicatrization by granulation. The former will be the easiest, unless the form of the tumor readily allows of the latter plan being employed, at the same time using a simple antiseptic mouth-wash and giving attention to the patient's general health.

Book Notices.

A Treatise on Pharmacy: designed as a Text-Book for the Student, and as a Guide for the Physician and Pharmacist. Containing the Officinal and many Unofficinal Formulas, and Numerous Examples of Extemporaneous Prescriptions. By Edward Parrish, late Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy, etc. Fifth Edition, Enlarged and thoroughly Revised. By Thomas S. Wiegand, Graduate of the Philadelphia College of Pharmacy. With Two Hundred and Fifty-six Illustrations. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxiv-17 to 1090, inclusive.

Parrish's "Pharmacy" is pre-eminently a work for the apothecary. It does not in any great degree meet the needs of a student of medicine, for it does not give him the physiological or therapeutical facts which he should have prominently set before him. Nor, again, is it likely to be of service to the chemist, for, although it necessarily contains a great deal of chemistry and many chemical data, the latter are exhibited according to an empirical arrangement, which doubtless facilitates the work of memorizing, but certainly confuses chemical relations. For instance, to group together in one list formic, succinic, aconitic, and lactic acids (p. 530) is misleading to the student of chemical systems Still more so is the inclusion in one chapter of such dissimilar substances as cotton, charcoal, acetic acid, and creasote, while carbolic acid is reserved for another chapter, in which it is associated with hydrocyanic and valerianic acids.

Of course, in following this order, so anomalous to the chemical mind, the authors have a distinct object in view—that of grouping together objects of similar origin. But, inasmuch as chemical details are so abundantly given, it would surely have been well to indicate a little more clearly the natural order and the structural relations which these substances bear to each other.

A more serious objection than that of faulty arrangement attaches to the chemical part of the work. Apart from the introduction of substances which are not certainly known to exist (a fault almost unavoidable in a work of this character), and apart from some curiosities of chemical nomenclature, there are errors of much less venial character in the matter of chemical formulæ. The authors have neither entirely retained the old system of chemical notation, nor entirely adopted the new. In the same list, therefore (particularly in the case of the carbohydrates), we find formulæ in both the old and the new notation placed side by side without any sign to indicate which method is employed. Such confusion is highly misleading to the novice, and is indefensible in a work having any pretense to scientific accuracy.

Much more satisfactory than the section on organic chemistry is that devoted to the metallic elements and their compounds used in medicine. This is scientifically arranged, accurate, and well brought up to date.

The remainder of the book—that part which is directed especially to the student of pharmacy—contains a description of pharmaceutical processes and of the various preparations and their manufacture. This part is certainly very well done. It has been revised to accommodate it to the last edition of the Pharmacopœia, and seems to leave nothing to be desired as regards either fullness or accuracy. It is this portion of the work which constitutes its value for the student, and which has created a demand for it sufficient to call out five editions. Such a popularity renders extended commendation superfluous, and leaves the reviewer only the ungracious task of pointing out the deficiencies in an otherwise excellent treatise.

A Practical Treatise on Massage, its History, Mode of Application, and Effects, Indications, and Contra-indications, with Results in over Fourteen Hundred Cases. By Douglas Graham, M. D., Fellow of the Massachusetts Medical Society. New York: William Wood & Co., 1884. Pp. x-286.

Dr. Graham has performed a valuable service to the profession in thus collecting the results of the massage treatment in a great variety of cases. We think that he has been judicious in declining to illustrate his work, since, as he says, woodcuts give but a poor idea of the technique of the process. He divides his book into sixteen chapters, in the first two of which he gives an interesting review of massage, tracing the practice back to the early Aryan nations. In the third chapter he carefully describes the *modus operandi*, and rightly says that no physician should think it beneath his dignity to learn and apply the method in suitable cases. The author's remarks upon the physiology of massage are perhaps tinged with a little too much of that enthusiasm with which physicians come to regard a method of treatment which they have practiced long and successfully. Regarding the value of massage in neurasthenia, most readers will agree with Dr. Graham. The chapter upon "Massage of Internal Organs" seems to us rather more encouraging than the facts warrant.

Three chapters are devoted to the treatment of affections ot the nervous system. The most useful chapters are those which refer to joint disease; the importance of the "movement cure" in these cases is unquestionable.

The closing chapter treats of Massage of the Head, Face, Eyes, Ears, and Throat, with which the author seems to have had only a limited experience.

In thus hastily mentioning Dr. Graham's book we can not do justice to the author's research or experience, both of which have been great. Although many readers will be inclined to differ with him as to the degree to which massage is useful in

* Bryant, Amer. ed., 1873, p. 242.

† Billroth, Amer. ed., 1875, p. 606.

medicine, few will doubt that by its systematic application, as he recommends, far more will be accomplished than is now attained by the unskillful attempts of physicians who have not learned to regard the treatment in the light of a scientific procedure.

The Elements of Physiological Physics: an Outline of the Elementary Facts, Principles, and Methods of Physics; and their Applications in Physiology. By J. McGregor-Robertson, M. A., M. B., C. M., Muirhead Demonstrator of Physiology, etc., in the University of Glasgow. Illustrated with 219 Engravings on Wood. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xii–528.

This handy little book is the result of a series of demonstrations given by the author to his class in the physiological department of Glasgow University. The various branches of physics are taken up, one after another, the main facts of each briefly stated, the apparatuses needed to illustrate the same described, and the physiological application of the facts and adaptation of instruments noted.

Of the 514 pages of reading matter, 174 are devoted to the study of magnetism and electro-physiology. Nor is this disproportionate to the importance of this interesting branch of the subject. Electro-physiology and electro-therapeutics, it must be confessed, are yet but imperfectly understood, and inadequately appreciated. The space devoted to them in this work is very fairly filled, but contains nothing novel and lacks practical details of some instruments of precision and convenience which students on this side the water have come to look upon as standard and essential. This is particularly true as to galvanometers.

On the other hand, under the head of Blood Pressure, more than a dozen different instruments of measurement and precision are described, many of which are anything but practical in the hands of medical students, and of value only to experts and specialists.

In other departments the work seems to have been carefully prepared, and in all essentials to be abreast with the progress of the day in physical science. If we were to venture any criticism on the work as a whole, it would be that the hasty glance we have been able to give it leaves the impression that it is not full enough for a general treatise, and yet is too heavy for a handbook. As a compendium for the accommodation of the busy practitioner who wishes to review the subjects treated, but has no time to devote to an elaborate treatise, this compact and well-printed volume will be of value.

The Elements of Pathology. By Edward Rindfleisch, M. D., Professor of Pathological Anatomy in the University of Würzburg. Translated from the First German Edition by William H. Mercur, M. D. Revised by James Tyson, M. D., Professor of General Pathology and Morbid Anatomy in the University of Pennsylvania, etc. Philadelphia: P. Blakiston, Son, & Co., 1884. Pp. 283. [Price, $2.]

"This little work does not pretend to be a text-book," says the author in his preface. This we must bear in mind in judging of its merits before we accuse him of having written an inferior manual. He adheres throughout to his intention of presenting only an outline of the science, but, as an outline, it is certainly not unworthy of careful perusal.

A glance at the table of contents shows us the general plan of the book. Beginning with the first part, which he calls the "Local Outbreak of Disease," the author touches briefly on the hyperæmiæ, inflammation and its results, and tumors in general.

In Part II, which treats of the Anatomical Extension of Disease, he considers metastasis, fever, and irritation of the nervous system.

Part III includes, under the head of "Physiological Extension of Disease," the disturbances of nutrition, of the circulation, of the blood (called "vegetative disturbances"), and of the nervous system, which are characterized as "animal disturbances."

The concluding section treats of traumatic diseases, parasites, and defects of development. There are no illustrations.

When we say that the translator has rendered the German of Rindfleisch (and it is often ponderous) into clear and intelligible English, we give him no scant praise. Most careful, too, has been the work of revision.

Dental Surgery for Practitioners and Students. By Ashley W. Barrett, M. B. (Lond.), M. R. C. S., L. D. S., etc. Philadelphia: Presley Blakiston, Son, & Co., 1885. Pp. xii–83.

This little work aims to convey enough practical information upon dentistry to serve the purposes of the general practitioner and no more. Naturally, but little space is required. It deals with the eruption of the teeth, lancing the gums, some of the more common deformities, and the extraction of carious teeth. Even then it goes much further into the subject than any general practitioner would go in this country, for few men who were not dentists would undertake here to fit a plate to the mouth for the correction of an abnormal position of the permanent teeth. What has been written is all interesting, but it would seem that the choice of subjects might be much improved. Some matters of interest to the general practitioner have in many cases been omitted.

The Microscope in Botany. A Guide for the Microscopical Investigation of Vegetable Substances. From the German of Dr. Julius Wilhelm Behrens. Translated and edited by Rev. A. B. Hervey, A. M., assisted by R. H. Ward, M. D., F. R. M. S. Illustrated with Thirteen Plates and One Hundred and Fifty-three Cuts. Boston: S. E. Cassino & Co., 1885. Pp. xv–466. [Price, $5.]

The scope of this work is not clearly set forth in the title. The subject of botany occupies only its second and lesser portion, and this is still further diminished by the presence of forty-three pages of valuable matter upon microscopical reagents. The larger part of the book is occupied with a description of the microscope and its accessories, and with the preparation of microscopical objects. It is the most satisfactory work upon these subjects that we have ever seen. It will be especially valuable for beginners in the use of the microscope, and is the only book with which we are acquainted which describes those principles which are fundamental to the microscope, and which are essential as a foundation for work with that instrument in a manner which is intelligible to the average mind. Leaving the botanical portion entirely out of consideration, it is a book which will be a useful addition to every student's shelves, and is to be recommended without qualification.

BOOKS AND PAMPHLETS RECEIVED.

Facts and Mysteries of Spiritism: Learned by a Seven Years' Experience and Investigation. With a Sequel. By Joseph Hartman. Philadelphia: Thomas W. Hartley & Co., 1885. Pp. xii–378. [Price, $1.50.]

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.
NEW YORK, SATURDAY, DECEMBER 19, 1885.

THE MEDICAL SERVICE OF THE NATIONAL GUARD OF THE STATE OF NEW YORK.

We have been much interested in the reports of the Surgeon-General of the State of New York, Dr. Joseph D. Bryant, for the years 1883 and 1884, included in the reports of the Adjutant-General for those years. Since the close of the War of the Rebellion, there has been comparatively little real duty devolving upon the Surgeon-General of the State, and we are glad to see that Dr. Bryant, whose appointment to the office we commended at the time it was made, has made work for himself, so to speak, by preparing elaborate annual reports on the affairs of the National Guard from a medical point of view, especially the sanitation of the State Camp of Instruction at Peekskill.

The sanitary affairs of individual bodies of troops during their stay at the camp are fully reported upon, and it is gratifying to learn that thus far no case of disease has come to light that could fairly be imputed to any peculiarity of the locality. The reports upon the experiences of these various organizations are preceded by some excellent remarks concerning the selection of regimental medical officers. Too often, as Dr. Bryant says, a colonel looks upon these members of his staff as ornamental luxuries rather than necessities, their chief function being supposed to be to assist in making up a full staff on parade and at inspections, while that of attending upon those of the men who may require their professional services is viewed as nothing more than incidental. Hence it happens that men are recommended to the Governor for appointment as medical officers of regiments quite as much out of consideration for their showy qualities as with reference to their actual fitness for the duties. This, of course, is all wrong, and it is to be hoped that Surgeon-General Bryant's views on the matter will make an impression on commanding officers.

The unthinking are apt to descant somewhat disparagingly upon what they term the tenderness of the National Guardsmen as compared with regular soldiers, forgetful, apparently, of the fact that in actual warfare it is only the troops whose service dates back a considerable length of time that can be counted on to endure the hardships of forced marches, and that the best men in the world can not be taken from civil life and at once put on full military duty. It is indeed most unjust and foolish to impute effeminacy to a body of militiamen simply because they require to be handled tenderly during their brief sojourn in camp or on the occasion of long marches and annoying delays on parade; on the contrary, the prerogative and the duty of the medical officer to mitigate the rigors of such an occasion ought to be more generally recognized. As Dr. Bryant says, the ordering of commands to appear in white trousers for a public parade on a cold, windy November day, when the men's bodies become hot and perspiring, while their legs are cold and clammy, on account of the illogical distribution and quality of the clothing, should be opposed by the medical officers, and commanders should be impressed with the fact that, while pomp and display constitute something of military glory, the health and comfort of the men are infinitely more important. Regimental surgeons should not wait for commanding officers to ask them for their advice as to such matters, but should obtrude it upon them, and public opinion should hold that commander to a strict accountability who should dare to disregard the medical officer's protests.

Dr. Bryant makes a number of excellent suggestions as to providing for immediate medical attention to soldiers in need of it, pending the arrival of the surgeon. For example, he says, the first sergeant of each company should be provided with a few simple remedies, the doses and general applications of which should be instilled into his mind, and he should be taught, among other things, to distinguish pallor from cyanosis, and to treat the patient accordingly. It is urged, too, that during rifle practice it is not enough that the surgeon should be somewhere on the grounds—he should be at the butts, where he may be needed at any instant and when there is no time to be wasted in searching for him.

MINOR PARAGRAPHS.

THE HARMLESS LUNATIC.

Those persons who believe that a lunatic should not be deprived of his liberty until he has committed a murder or two have doubtless been edified by the accounts of the recent achievements of a man in Norristown, Pa., who played the part of a demon until he was overpowered and "held by four men while a physician prescribed medicine to render him harmless for the time." It is naively added that he is "subject to such attacks." Norristown, by the way, is an asylum town.

"CROWNER'S QUEST LAW."

The newspaper accounts of the contention between two coroners as to whose "case" the death of Mr. William H. Vanderbilt was show something bordering unpleasantly on a quarrel, and, worse than that, they show the unsatisfactory state of the law which defines the coroners' jurisdiction. Why, for instance, a physician can not certify as to the cause of death unless he has seen the deceased within the twenty-four hours preceding the fatal issue, is not at all clear to the non-official mind.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 15, 1885:

DISEASES.	Week ending Dec. 8.		Week ending Dec. 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	0	1	0
Typhoid fever	18	5	16	5
Scarlet fever	25	8	50	5
Cerebro-spinal meningitis	4	4	3	3
Measles	10	1	6	2
Diphtheria	92	45	75	33
Small-pox	12	1	5	1

Trichiniasis is reported to have attacked seven members of a family living in Tarentum, Pennsylvania, in consequence of their having eaten of a salad containing raw pork.

The American Public Health Association.—The committee on the disinfection of rags, appointed at the Washington meeting last week, was instructed to investigate the matter thoroughly, and report at the next annual meeting.

The Health of San Francisco.—It appears by the Health Department's "Condensed Statement of Mortality" that the total mortality for the month of November was 421, including 69 deaths from zymotic diseases, 75 from constitutional diseases, 210 from local diseases, 46 from developmental diseases, 18 from violence, and 3 from causes not ascertained. During the corresponding month in 1884 the deaths numbered 379.

The Massachusetts State Board of Health, Lunacy, and Charity has just issued the Supplement to the Sixth Annual Report, containing the reports on public health. The document contains the following papers: "The Sanitary Condition of School-houses in Massachusetts," "Report of the Analysis of Food and Drugs," "Summary of the Weekly Mortality Returns of Massachusetts Cities and Towns," "The Report upon Illuminating Gases," "Epidemic Cholera," "Disinfectants," and "The Health of Towns." There is a large amount of valuable matter, not only to the profession, but to the general public.

The late Mr. Vanderbilt's Bequests include one of $100,000 to St. Luke's Hospital, and one of $50,000 to the Home for Incurables.

The Manhattan Hospital, at the corner of Tenth Avenue and One Hundred and Thirty-first Street, was opened on Monday.

Personal Items.—Among the passengers by the steamship Etruria, which arrived at this port last Sunday, were Dr. W. S. Halsted, of New York, and Dr. G. M. Sternberg, of the army.

The Newark Outbreak of Hydrophobia seems still far from subdued, although all sorts of barbarous means are resorted to for exterminating the dogs of the town. Several persons have been bitten since the four children sailed for Paris, some of whom seemed inclined to betake themselves to M. Pasteur at once, while others, notably a veterinarian who received his injury while attempting to render professional services to a dog, put their trust in cauterization.

Composite Photographs of Skulls.—We learn from the "Medical Times and Gazette" that Mr. Francis Galton, F. R. S., the president of the London Anthropological Institute, lately exhibited to that body, on behalf of Surgeon John S. Billings, of the United States Army, a collection of twenty composite photographs of skulls, forming four series, referring respectively to Sandwich Islanders, ancient Californians, Arapahoe Indians, and Witchitaw Indians. Each composite was the mean of six skulls of adult men.

The Mount Olivet Crematory can not be said to be in perfectly successful operation yet, if we may judge by the newspaper reports of the state of the "ashes" of Eugene Lievre, whose body was subjected to its action last week. It is said that a piece of the forearm, six inches long, was still so firm when the residue was withdrawn that it could be broken only by the use of two hands.

Another Harmless Lunatic.—In another column reference is made to the freaks of a lunatic in Norristown, Pa. This time the story comes from Philadelphia, where, on Wednesday last, the services of several policemen were required to restrain the suicidal frenzy of a maniac, who used his knife on one of the policemen, between his repeated incisions of his own throat and body, having first attempted to decapitate his wife, who, however, managed to escape.

College of Physicians and Surgeons; Medical Department of Columbia College.—At a meeting of the Board of Trustees, held December 15, 1885, the following preamble and resolutions were unanimously adopted:

Whereas, By the death of Mr. William H. Vanderbilt the cause of medical education in this country has lost one of its first conspicuous benefactors; and

Whereas, It becomes the duty of the Trustees of the College of Physicians and Surgeons, which was the object of his sagacious benevolence, to express their deep sense of the debt due to his memory; therefore

Resolved, That Mr. Vanderbilt's gift toward the advancement of medical knowledge reaches a higher mark in the intelligent disposition of wealth than has often been attained by public benefactors, for it recognizes science as the handmaid of humanity, and acknowledges the benefits of the healing art in controlling human misery and enhancing human happiness.

Resolved, That it is a source of profound regret to this board that Mr. Vanderbilt's life was not spared to witness the completion of the college building which his generous endowment projected, and which will become his most worthy and enduring monument.

Resolved, That the seresolutions be inscribed upon the minutes of this board, and that a copy be sent to the family of the deceased, with the assurance of our respectful sympathy for them in their great affliction.

[Signed] J. C. Dalton, M. D., *President.*
George G. Wheelock, M. D., *Registrar.*

The New York County Medical Association.—At the next meeting, to be held at the Carnegie Laboratory, on Monday evening, December 21st, Dr. J. R. MacGregor will read a paper on "Insanity and Public Opinion," and Dr. I. B. Read one on "Double Popliteal Aneurysm." Dr. J. W. S. Gouley will present four specimens of papilloma of the bladder.

A Victim of an Experiment.—Dr. Daniel Carrion, an esteemed Peruvian physician, lately lost his life in consequence of having inoculated himself with the blood of a child suffering with the disease known as *verruga peruana*. According to the "Union médicale," he performed the experiment for the purpose of demonstrating the identity of the disease with *fiebre anemizante*, or *fiebre de la Oroya*. The demonstration was successful, but it cost the life of the experimenter.

The Medico-Chirurgical College of Philadelphia.—Section IV of the Pennsylvania Registration Law of 1881 requires that diplomas from outside the State must receive the indorsement of a recognized medical faculty within the State before registration; but, before giving such, the faculty must be satisfied as to the qualifications of the applicant; and, as the indorsement of a diploma is an acknowledgment of the qualifications of its holder as well as of its genuineness, the faculty of this college desires to announce that it will indorse no diploma for registration until the holder thereof passes a satisfactory medical examination. The fee for such examination is $30.

The College of Physicians of Philadelphia.—At the December meeting of the College the standing committees presented their annual reports:

The Library Committee reported that the library now contained 33,686 volumes and 1,393 unbound pamphlets, an in-

crease in the year of 2,592, as compared with 1,261 in 1884, and 869 in 1883.

The books were classified as follows:

General Library	18,069
Lewis Library	8,736
On special deposit:	
Mütter Museum	86
S. D. Gross Library	5,130
The Hodge col'ection	1,665
Total	33,686

The library had received 184 current periodicals devoted to medicine and the collateral sciences. The number of books taken out during the year, not including the large number which had been consulted in the rooms, was 1,231. In the General Library all the books were catalogued with the exception of the dictionaries, journals, reports, and pamphlets. In the Lewis Library, all the books were catalogued to date. During the year additional bookcases had been erected in the large hall, affording accommodation for about 2,600 books. These cases were now full.

The Committee on Publication reported that during the year papers had been read by fourteen Fellows. In addition to these, a paper by Dr. Graham and one by Dr. Orville Horwitz had been communicated by Dr. J. M. DaCosta, and an address on "Photography of the Larynx" had been read by Dr. Theodore R. French, of Brooklyn. The total number of pages in the volume of "Transactions" for 1885, to date, was about 232. Through the generosity of the President, the committee had been enabled to employ a stenographer and thus obtain a full report of the discussions.

The Committee on the Directory for Nurses reported that the number of nurses registered December 1, 1884, was 419. The present number was 475, showing a gain of 56. During the year the loss by dismissal, resignation, death, and removal had been 18. The number of applicants for registration had been 118, of whom only 68 had been registered. The largest number of nurses sent out in any one month was in January, 1885, 119; the smallest in August, 47. The total number of nurses supplied during the last four years had been in 1881–'82, 342; 1882–'83, 733; 1883–'84, 913; 1884–'85, 1,003. Seventeen wet-nurses had been furnished during the year. The committee had recently assisted the New York Academy of Medicine in establishing a similar directory for nurses in that city.

Medical Men in Parliament.—The "Medical Times and Gazette" announces that the following-named graduates in medicine have been elected to the new House of Commons: Charles Cameron, M. D., Glasgow; Robert Farquharson, M. D., F. R. C. P., West Aberdeenshire; Robert Bannatyne Finlay, M. D., Q. C., Inverness Burghs; Balthazar W. Foster, M. D., F. R. C. P., Cheshire; Henry Mitchell, F. R. C. S., Glasgow; Sir Guyer Hunter, M. D., F. R. C. P., K. C. M. G., Hackney; Sir J. J. Trevor Lawrence, Bart., M. R. C. S., Surrey; R. Macdonald, M. D., Ross and Cromarty; Kevin Izod O'Doherty, F. R. C. S. I., North Meath; L. J. N. Tanner, L. R. C. P., L. R. C. S., Mid-Cork; and Philip J. Vanderbyl, M. D., M. R. C. P., Portsmouth. The contest in which Mr. Erichsen was engaged had not yet come off. Mr. Ernest Hart, Dr. Herbert Watney, Dr. Alfred Carpenter, Mr. Peter Royle, Dr. Danford Thomas, and apparently Dr. R. D. Lyons, have been defeated. Among the scientific men elected who are not medical graduates are Sir Henry Roscoe, the chemist, Sir Lyon Playfair, and Sir John Lubbock, who, as our contemporary remarks, "will form a scientific trio whom it would be difficult to match."

Obituary Notes.—The death of Dr. John W. Sawyer, of Providence, R. I., took place on Monday last, in his fifty-first year. He was born in Danvers, Mass., in 1834, was graduated from Harvard Medical School in 1859, and entered the Butler Hospital for the Insane, in Providence, as assistant physician. He then became assistant physician to the Wisconsin Hospital for the Insane, and subsequently returned to the Butler Hospital, of which he was superintendent at the time of his death. He was a member of the Providence Medical Association, of which he was twice president, and also a member of the Rhode Island Medical Association.

Death of Dr. Albert H. Smith, of Philadelphia.—Although it comes as a release from a long and painful illness, Dr. Smith's death, which took place on Tuesday, will be generally recognized in the profession as involving the loss of one of the most accomplished and most esteemed of American obstetricians.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 29 to December 12, 1885:*

Vickery, R. S., Major and Surgeon. Relieved from the assignment as Acting Medical Director, Department of the Columbia, to date the 16th inst. S. O. 200, Department of the Columbia, November 23, 1885.

Birmingham, H. P., First Lieutenant and Assistant Surgeon. Ordered for duty at Camp Grant, Riverside Park, New York city. S. O. 256, Department of the East, December 4, 1885.

Bushnell, George E., First Lieutenant and Assistant Surgeon. Ordered for duty as Post Surgeon, Fort Preble, Me. S. O. 256, Department of the East, December 4, 1885.

Wilson, William J., Captain and Assistant Surgeon. Ordered for duty as Post Surgeon, Plattsburg Barracks, N. Y. S. O. 256, Department of the East, December 4, 1885.

Appel, D. M., Captain and Assistant Surgeon. Ordered for duty at Jackson Barracks, La. S. O. 256, Department of the East, December 4, 1885.

Everts, Edward, First Lieutenant and Assistant Surgeon. Ordered from Department of the Columbia to Department of Arizona. S. O. 279, A. G. O., December 5, 1885.

Polhemus, A. S., First Lieutenant and Assistant Surgeon. Relieved from duty at Presidio of San Francisco, Cal., and ordered for duty as Post Surgeon at Fort Halleck, Nev., relieving Acting Assistant Surgeon Loren N. Clark, U. S. Army. S. O. 113, Department of the Columbia, November 30, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending December 12, 1885.*

Aulick, Hampton, Surgeon. Ordered to the Alliance as relief of Surgeon G. P. Bradley.

Bradley, George P., Surgeon. Ordered to Naval Hospital, Philadelphia.

Shafer, Joseph, Assistant Surgeon. Detached from Naval Hospital, Philadelphia, and ordered to the Minnesota.

Gaines, J. H., Past Assistant Surgeon. Detached from Naval Hospital, Washington, and ordered to the Dolphin.

Lippincott, George C., Passed Assistant Surgeon. Detached from Navy-Yard, Washington, and to wait orders.

Deane, C. W., Passed Assistant Surgeon. Ordered to the U. S. Receiving Ship Dale as relief of Passed Assistant Surgeon G. P. Lumsden.

Lumsden, G. P., Passed Assistant Surgeon. Ordered to Naval Hospital, Washington.

Lovering, P. A., Passed Assistant Surgeon. Detached from U. S. Receiving Ship Wabash, and to wait orders.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the three weeks ended December 12, 1885 :*

Wyman, Walter, Surgeon. Granted leave to attend meeting of American Public Health Association. December 3, 1885.

Benson, J. A., Passed Assistant Surgeon. Granted leave of absence for fifteen days. November 28, 1885.

Armstrong, S. T., Passed Assistant Surgeon. Granted leave of absence for eight days. November 30, 1885.

Wasdin, Eugene, Assistant Surgeon. Granted leave of absence for thirty days. November 28, 1885.

Watkins, R. B., Assistant Surgeon. To proceed to Galveston, Texas, for temporary duty. November 30, 1885.

Yemans, H. W., Passed Assistant Surgeon. Granted leave of absence for fifteen days. December 7, 1885.

Bratton, W. D., Assistant Surgeon. When relieved, to proceed to San Francisco, Cal. December 12, 1885.

Norman, Seaton, Assistant Surgeon. Appointed an Assistant Surgeon, December 11, 1885. Assigned to duty at New York, N. Y., December 12, 1885.

Society Meetings for the Coming Week:

Monday, *December 21st:* New York County Medical Association; Medico-Chirurgical Society of German Physicians; Hartford, Conn., City Medical Association; Chicago Medical Society.

Tuesday, *December 22d:* New York Dermatological Society; New York Surgical Society; Buffalo Obstetrical Society (private); Medical Society of the County of Lewis (quarterly), N. Y.

Wednesday, *December 23d:* New York Pathological Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society (conversational).

Thursday, *December 24th:* New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); Harlem Medical Association of the City of New York; New York Orthopædic Society; Brooklyn Pathological Society; Roxbury, Mass., Society for Medical Improvement (private).

Friday, *December 25th:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, *December 26th:* New York Medical and Surgical Society.

Letters to the Editor.

THE DISINFECTION OF RAGS AT THE PORT OF NEW YORK.

To the Editor of the New York Medical Journal:

Sir: The medical profession, of which you are a representative, is rightly regarded as the defender of the public against quacks and impostors. The confidence it has so well earned in this direction carries a certain responsibility with it, because it makes it very desirable for quacks to gain the aid of the profession where that can be done.

It is in view of this responsibility that I wish to lay before you some facts touching the importation of rags (the raw material of paper) into the port of New York. Under the law of the State, as now interpreted and practiced, it is within the discretion of the Health Officer of New York to forbid the landing of imported rags, no matter whether they be brought from infected districts or not, or whether there be reason to suppose that they are themselves infected or not, unless they are disinfected to his satisfaction. This is the accepted law and the actual practice at this port, and this extraordinary discretion is subject to no accountability or control except by the Board of Quarantine Commissioners, and in their hands the power of control, as a matter of fact, is not exercised.

Now, the manufacturers of paper contend that this practically unchecked and arbitrary power in the Health Officer is subject to grave abuse, and that it is unnecessary to the protection of the public health.

The manufacturers of paper do not wish to import disease. If they had no other reason for not wishing it, it is enough that it would be greatly against their interests to do so, for, as soon as it was known that they had done so, their employees would leave, their mills would be closed, and their importations would be stopped. They have been taught by experience to doubt whether rags can be thoroughly disinfected, especially in the bale. They are willing and desirous, if rags can be shown to be infected or to have been gathered in infected districts, that these rags shall be destroyed. But they protest that it is a gross outrage on them and on the public that their property, coming from uninfected districts, in ships bearing clean bills of health, shall be subjected to a patent disinfecting process. They demand, and they think they have a right to demand, that, if "*disinfection*" be required, it may be done by some other than a patented or secret process. Nominally a choice is given between two processes; in reality only one can be applied, and that one belonging to what, for want of a better term, I shall call the "Quarantine Ring."

This is being done now and here in the name of "sanitarian" vigilance and "humanitarian" zeal, and the medical profession are asked to approve it. I would respectfully ask them to examine carefully and consider candidly these facts before lending their powerful support to such a scheme.

I remain, with the highest respect,

Your obedient servant,

Augustine Smith,

Vice-President American Paper-Makers' Association.

TYPHOID AND TYPHO-MALARIAL FEVERS.

Seneca Falls, N. Y., *December 12, 1885.*

To the Editor of the New York Medical Journal:

Sir: At the meeting of the New York State Medical Association, Third Branch, Dr. Elsner, of Syracuse, read an essay on "Typhoid Fever as we see it in Central New York," and I saw in your Journal of the 28th the published paper. I read it with much interest. It is well written and describes the character of the diseases of this section very minutely and well, and I would let it go by without comment if I was not fearful it might lead some young practitioner into an error by making him believe he was treating typhoid fever when it is malarial fever, or the bilious remittent of our forefathers. We have the same class of fevers here that they have in Syracuse. The marshes of Cayuga Lake and the Seneca River are filled with malaria, and all our diseases—pneumonia, dysentery, enteritis, etc.—partake of a remittent character. These fevers of which he speaks are the most common of any diseases we have. They

come on just as he describes, but, if taken early, can be broken up; in fact, they never reach the typhoid state unless treated by some homœopath, or the patient has tried to treat himself for a week or ten days. I will not say *never*, because there are a few which are taken violently, and will pass into the typhoid condition in spite of all you can do. This proportion of cases is very small—perhaps five per cent. They then go on fourteen, twenty-one, or twenty-eight days in that typhoid condition, with livelier delirium than in typhoid fever proper, less of the bowel lesion, and less subsultus tendinum. I hope my friend Dr. Elsner may never strike an epidemic of typhoid fever "Simon pure"; if he does, he will be led to know that our typho-malarial fevers of Central New York are about as near typhoid fever as chicken-pox is like the deadly confluent small-pox.

I am very respectfully yours, etc.,

Elias Lester, M. D.

Proceedings of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of December 9, 1885.

The President, Dr. John A. Wyeth, in the Chair.

Bilateral Perinephritic Cysts.—Dr. T. M. Prudden reported on the specimens presented for a candidate by Dr. Boldt at the last meeting. The conditions found, he said, were very interesting. One of the tumors had occupied nearly half the right side of the abdominal cavity; there was a similar tumor on the left side, but smaller. One contained about 300 c. c. of a gelatinous fluid; the other contained over a litre. In the former the surface of the kidney was thickly besprinkled with small cysts, containing fluid like that in the larger cyst. The cortex of the kidney was about 1 ctm. in thickness; the pelvis was largely dilated; the ureters were also dilated. There seemed to be a capsule over the kidney, which in places was two or three times as thick as normal. One side of the kidney was still adherent to what formed the wall of the cyst; the other was free. The free side was smooth and contained but very few small cysts. On this side there was very marked chronic interstitial nephritis; but very little existed on the other side. Both sides of the second kidney were free, and covered by sub-capsular and intra-capsular cysts containing fluid; a cyst 7 ctm. in diameter was connected by a small opening with the one which held a litre of fluid. There was very little interstitial nephritis. The convoluted tubules contained a kind of soft mucous tissue, having been dilated by a gelatinous material similar to that contained in the large cyst, and in their near neighborhood there were cysts which had lost their tubular character. Thus there were two cystic kidneys, with chronic nephritis. Everything seemed to indicate that the contents of the outer cyst had insinuated their way into the tubules. There were also some crystals of hæmatoidin in the vicinity of the cysts within the kidney. It was impossible to say how the cysts originated, or whether or not they were congenital.

Sarcoma of the Liver.—Dr. H. J. Boldt presented a part of a sarcomatous liver, the entire organ having weighed a little more than nineteen pounds. The interest in the case regarded difficulty of diagnosis, the physical signs pointing to either amyloid or malignant change in the liver, while the history led to the suspicion of syphilis.

Cystic Degeneration of both Kidneys and of the Liver.—Dr. J. W. Roosevelt presented the specimens, and remarked that he had been able to find only four recorded cases of the kind. The patient from whom the specimens were removed was a laborer, aged thirty-seven years, who was admitted into Roosevelt Hospital July 6, 1883. He was a hard drinker; he denied syphilis. He had been ailing for a year or longer; complained of palpitation of the heart and of seeing muscæ volitantes. He had also had dyspnœa on exertion, headache, œdema, etc. On admission, he was poorly nourished and his face was flushed. He had no œdema, but some dyspnœa and a slight cough. The urine, which was of low specific gravity, contained a small amount of albumin. The liver was enlarged, and there was enlargement of the superficial abdominal veins. July 12th he suffered more and more from dyspnœa, became comatose, and died from pulmonary œdema. The interesting lesions were in the liver and kidneys. The liver was enlarged and was filled with cysts varying in size from being only visible to the size of a lemon, some containing a thicker and darker fluid than others. Both kidneys were very much enlarged, preserved partially their normal outline, and had been converted into masses of cysts. To the naked eye, there was no normal kidney tissue remaining, but the specimens would be examined by the Committee on Microscopy. The ureters were not dilated.

Dr. Roosevelt also presented a mass of cysts occupying the place of a kidney, found in the museum of the Roosevelt Hospital, unaccompanied with any history.

Stone in the Bladder.—Dr. Roosevelt presented further a bladder with greatly thickened walls, containing a stone of about the size of a walnut; also the right kidney reduced to a small cyst, and the left kidney much enlarged—the so-called "surgical kidney"; the pelvis and ureter were dilated. Dr. Roosevelt thought the nucleus of the stone might have developed within the kidney, and, after destroying that organ, have worked its way into the bladder. The patient's condition did not warrant an operation when he was admitted into the hospital, and he died shortly afterward.

Osteitis of the Fibula.—Dr. Wackerhagen presented the lower end of a fibula removed for necrosis from a girl thirteen years of age. About three years ago she sustained a contusion on the outer aspect of the right ankle; afterward an abscess broke, and trouble existed until about seven months ago, when the speaker exsected two inches and a half of the lower end of the fibula and scraped the astragalus. There was no history of tuberculosis.

White Renal Infarctions, etc.—Dr. L. E. Holt presented the heart and kidneys of a child which died, aged seventeen months, in the Infant Asylum. At the cutting of each tooth there had been an unusual amount of cerebral irritation; on the last occasion this was very marked; on the eighth day the temperature rose to 104° F., the child became comatose, the pupils were contracted, and on the tenth day, three hours before death, there was marked cyanosis. At the autopsy the vessels in the right hemisphere of the brain were found greatly engorged, and in marked contrast with those in the left hemisphere, which was anæmic. In the sinuses on the left side of the brain there were firm decolorized thrombi; there were none on the right side. Both sides of the heart contained large, closely adherent clots, which were regarded as of ante-mortem formation. There was white infarction in both kidneys to a very marked degree, with commencing diffuse nephritis. The case was interesting in three respects: First, with regard to engorgement of the arteries on the right side of the brain, with absence of thrombi on that side, while there was apparently anæmia on the left side, with thrombi of the veins; second, with regard to evident ante-mortem heart clots; third, with regard to renal infarctions. For none of these conditions was there an apparent underlying cause.

Multiple Myomata of the Stomach and Bladder.—Dr. R. Van Santvoord presented a series of specimens removed from the body of a man aged seventy years. The brain was anæmic; the vessels at the base were slightly atheromatous, but quite brittle; there were one or two spots of softening on the cortex. There was straw-colored fluid in the pleural cavities, and cheesy nodules were found in the upper lobe of each lung; the pleuræ were adherent and thickened. The left cardiac ventricle was markedly hypertrophied; there was slight atheroma of the mitral valves; the aorta was calcified, and the same atheromatous process extended into the larger vessels of the neck. The radial arteries showed no marked amount of atheroma. In the lesser curvature of the stomach there was a saddle-shaped neoplasm, about two inches and a half in length, and about half an inch in thickness; it seemed to be chiefly muscular; the walls of the bladder and rectum also presented a muscular-like tumor, the microscopical examination of which had not yet been completed. The mesenteric glands were likewise thickened.

Physical Signs of Pneumonia involving the Anterior Surface of the Upper Lobe.—Dr. Van Santvoord presented a second series of specimens, from a man who had been sick seventeen days prior to admission into the Randall's Island Hospital. On his admission, Dr. Maxwell found marked dullness over the upper lobe of one lung, flatness over the lower lobe, absence of the respiratory murmur over the lower lobe, and marked amphoric breathing above. On the following day the amphoric breathing had disappeared over the upper lobe, bronchial breathing having taken its place. Flatness had disappeared over the lower lobe, and bronchial breathing was present where there had been absence of respiratory murmur before. The urine contained about one eighth albumin, blood casts, and free blood. The last day of his life the patient had three epileptoid convulsions, and died comatose. He was about sixty-five years of age. The autopsy revealed the arachnoid thickened by a chronic process. The pia was infiltrated with a gelatinous-looking lymph extending over the whole of the brain and into the spinal cord. There was gray hepatization over the right upper pulmonary lobe, very firm in character, and differing from that ordinarily seen in the upper lobe in that it approached very near the anterior edge of the lung. This point had an important bearing upon the physical signs. Dr. Janeway had called attention to the fact that in pneumonia of the upper lobe, in which the infiltration extended almost or fully into the anterior edge, there was very frequently not only amphoric respiration instead of bronchial, but also a cracked-pot percussion note transmitted from the bronchus. These cases not infrequently gave rise to errors in diagnosis. The speaker was unable to explain the cavernous breathing. In this case there was but little atheromatous change in the aorta, but it was very considerable in the radial arteries. The kidneys contained a few cysts, and examination would probably show chronic diffuse nephritis with an acute form ingrafted upon it.

Congenital Cartilaginous Bodies anterior to the Tragus.—The President presented three small bodies, probably yellow fibroid cartilage, removed from in front of the tragus of a young man whose father and aunt had had similar tumors. They were congenital.

Probable Tuberculosis Testis.—The President also presented a diseased testicle which would be examined by the Committee on Microscopy. The patient, fifty-five years of age, had been admitted into Mount Sinai Hospital December 7th. He had had hernia on the left side for twenty-five years. About seven months ago the left testicle became enlarged and gave slight pain. It increased gradually, and six weeks ago had extended upward into the inguinal canal, becoming harder and more tender. The patient had also been treated for posterior spinal sclerosis. On the 7th instant the President found the tumor as large as one's fist, extending into the inguinal canal. There was evidently fluid. The bowels were not free. It seemed possible that there was either hydrocele, simple periorchitis, or strangulated hernia. At the operation there was found a double cyst, the first outside the cord practically, which contained about an ounce of clear fluid, the second within the tunica vaginalis testis, which discharged about four ounces of fluid. There was no hernia present. The testicle and epididymis were enlarged, and, when they were removed, little blood escaped, a fact suggestive of necrosis of the testicle. There were, then, three possible conditions in the case, any one of which would have justified an operation. The nature of the disease of the testicle could not be determined until after a microscopical examination.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of December 1, 1885.

The President, Dr. W. R. Birdsall, in the Chair.

Unilateral Hallucinations.—Dr. William A. Hammond read a paper on this subject. [See page 649.]

Dr. Leonard Weber related the history of a case which he thought went to support the view which Dr. Hammond seemed to entertain, that unilateral hallucinations were not associated with disease of the special sense concerned, but with an affection of central origin. A man came under his observation in 1879, at which time he was thirty-seven years of age, strong, healthy, very active in business, but, in consequence of domestic trouble and mental strain, had begun to lose sleep, was sensitive to strong light, loud noises, etc., and from 1879 to 1881 was subject to hallucinations connected with the left ear. On going to bed he was unable to sleep for two or three hours because of whispering noises, growing louder and louder, heard in the left ear, and of two kinds, one soothing and the other mandatory. A careful examination by himself and by a specialist in diseases of the ear failed to reveal anything wrong connected with the auditory apparatus. When the patient's circumstances changed, and he was enabled to lead a peaceful life, the hallucinations disappeared, and had not returned.

Dr. E. C. Spitzka had not heard the entire paper, but, being familiar with the author's views regarding the function of the optic thalamus, he was somewhat surprised that he had not tried to harmonize his observed facts with the anatomical and physiological facts which had been incontestably established during the past decade. Lewes, upon whom Dr. Hammond probably rested chiefly for support of his views, expressed his ideas regarding the functions of the optic thalamus as many as twenty-five years ago, and what he wrote was mere guess-work. If he had been supported in part by recent accurate methods of research, such as the atrophy and other methods, it was a mere coincidence. The speaker's own views regarding hallucinations were directly opposed to those of Dr. Hammond. He believed that hallucinations had their seat in the cortex, and not in the optic thalamus or any of the lower ganglia. The optic tract and thalamus might have undergone secondary atrophy, following enucleation of both eyeballs, yet the person would be capable of having hallucinations, showing that hallucinations had not their seat in the optic thalamus. The case cited by Dr. Hammond, in which during her hallucinations the patient saw the figure of a man and woman, showed the exercise of mental qualities which could have their seat nowhere else than in the cerebral cortex. Dr. Hammond had asked whether he did not believe an hallucination to be something which had been previously registered in the memory and which was projected outward.

He would reply that, without quibbling about terms, that was precisely what he meant by an hallucination.

Dr. M. A. Starr related the facts in a case reported by Vetter, in which a patient having right hemianopsia imagined that she saw people sitting at her right side, which was the blind side. By a process of exclusion it was shown that the lesion could not have existed in the optic thalamus, but must have existed in the occipital lobe. In all probability the source of the hallucination in this case was cortical irritation. Certainly in a great many cases cortical irritation would produce hallucinations. This was observable in meningitis in which the optic thalamus was not implicated.

Dr. W. M. Leszynsky recalled the case of a woman, fifty years of age, in a lunatic asylum, suffering from mania, who was in the habit of sitting hours at a time with the left ear inclined toward a table, sending, she said, and receiving telegraphic communications. She did not receive the telegraphic communications with the right ear, which she said was only for general use. The hearing seemed to be normal; perhaps that in the left ear was a little more acute than that in the right ear.

Dr. Sachs referred to a case of hemiplegia with tumors in the optic thalamus, reported by Minot, and asked Dr. Spitzka whether he could imagine an excitation of the cerebral cortex giving rise to an image or hallucination, the revival of such image not being due to an antecedent peripheral irritation.

Dr. J. L. Corning asked why hallucinations which might be produced by impressions coming from the peripheral nerves might not also be produced by an irritation at any point in that peripheral tract, as in the thalamus? Everybody would admit that the higher forms of conception took place in the cerebral cortex.

Dr. C. L. Dana would like to hear the subject discussed which Dr. Hammond had probably wished to bring before the society, namely, the duality of the brain. So far as the mechanism of hallucinations was concerned, he thought all would agree with Dr. Spitzka that it was essentially in the cerebral cortex; but the exciting cause might be a peripheral irritation acting upon the psychopathic centers. As to the duality of the brain, he thought there were many more arguments against the proposition than for it; but the subject was one of great reach, and could hardly be discussed at this hour. The cases of hallucination cited did not, it seemed to him, prove much, because only a small part of the psychical mechanism was involved. On the other hand, the experiments of Dumont Paré proved little, because hypnotized subjects could be led to do almost anything by slight suggestion. But pathological observations, the results of hemiatrophies, or of tumors on one side of the brain, studies regarding language, etc., all went to show that the two cerebral hemispheres had certain distinct functions, and that there were not two halves of the brain each having about the same function.

Dr. Charles Heitzman said that, although he was not a specialist in this department, he had given considerable study to it, and he had got the impression that neurologists were not entirely clear in their ideas concerning the seat of irritation which caused hallucinations. Let the physiological fact be remembered that an impression upon our senses could be brought forward at any time in the shape of a protracted sensation or hallucination. Thus, a peculiar sound might be heard which was merely the image of a real sound, and constituted an hallucination. Everything which we had learned was registered in the brain, especially in the gray substance. In the case of the black cat, could the man have had an hallucination of a black cat if he had never seen a black cat? He doubted it. Wherever the center for the image of the black cat might be, if any portion of the nerve-tract leading from the retina to that center was disturbed, it would be likely to excite that center, and the image of the black cat would be revived. The special point of interest connected with the hallucinations related was that they were unilateral. He asked if that might not be explained on the supposition that the irritation, being upon one side, led to the center for the given image upon that side only.

Dr. Spitzka said, with regard to the duality of mind, that there could be little difference of opinion regarding the following facts: The two cerebral hemispheres were alike in structure, the variations being no greater than in other symmetrical organs, if allowance was made for a higher type of development; the hemispheres were united by a symmetrical commissure; they had corresponding peripheral tracts; they had about the same distribution of retinal fields; post-mortem examinations on the insane went to prove that the hemispheres were symmetrical; one hemisphere might be practically destroyed and yet the individual retain power to exercise the several faculties of the mind, such as reasoning, memory, judgment, etc.—not, however, that there would be no paralyses or other symptoms. But it was a different matter entirely when it was suggested that unilateral hallucinations could exist when the corresponding hemisphere was perfectly healthy.

Dr. Hammond, in closing the discussion, said it had not been his object to discuss specially the function of the optic thalamus. He might say, however, that he believed a person could have hallucinations without an optic thalamus at all, provided he had a cortex; but he believed also that he could have hallucinations without any cortex, provided he had an optic thalamus. In the former case the hallucinations would be due to a revival of past impressions; in the latter case they would be original, having nothing to do with former associations. A man without an optic thalamus could have an idea of a cat in the abstract, but he could not have an hallucination of a particular cat. He believed that ideation resided in the cortex. With regard to the duality of the mind, many arguments might be brought forward, but time would not permit.

BALTIMORE ACADEMY OF MEDICINE.

Meeting of December 1, 1885.

The President, Dr. J. J. Chisolm, in the Chair.

Evisceration of the Eyeball by the New Method.—The President related a case of evisceration of the eyeball after the plan recently recommended, which consisted in completely excising the cornea by means of a circular incision around its margin, the contents being then entirely removed, leaving the sclerotic intact. The advantage alleged for the operation was that the socket tissues were not disturbed; neither was the muscular apparatus of the eye interfered with; besides, the stump left made an admirable seat for an artificial eye. The operation itself was very simple, and could be performed much more expeditiously than complete enucleation, but convalescence was so very tedious, and at times gave rise to such painful and alarming symptoms, as had occurred in his case, that in future he should confine himself to the old plan of complete enucleation. It was his usual custom to allow a patient to go about his affairs very soon after the operation, at the outside in twenty-four hours, but in the evisceration operation, even up to the fourth day and later, there were such œdema and pain that he could not think of allowing the patient to be from under his observation. He had never had such an experience with the old method.

Dr. S. C. Chew wished to know if sufficient anæsthesia could be produced by the use of cocaine to enable one to perform this operation without pain to the patient.

The President thought not.

Paralysis from a Fall.—Dr. A. B. Arnold related a case which had occurred at Bay View Asylum a year before, in a woman five months pregnant. She fell from the second story window, striking upon the head; when picked up she was senseless, and remained so for three days. Among the consequences of the fall, abortion was brought on. At present she had paralysis of both lower extremities, and complete anæsthesia on the right side, and was deaf and blind on that side. She evidently had some spinal trouble, as she complained of that sensation so common in these troubles, "as if a belt were being drawn about her waist"; also had some enfeeblement of the sphincters of the bladder and rectum. In addition, there was a peculiar nervous jerking about the head, which had continued for a year.

The speaker thought the lesion was located about the inferior third of the internal capsule, extending up and involving the optic and auditory nerves at their point of crossing, and that the nerves of sensation which came off at that point were affected. He thought the symptoms justified this conclusion. The pupils responded normally to light. She had never had any trouble previous to the fall.

The President asked if any ophthalmoscopic examination had been made. He was prompted to ask this question by a case which had recently come under his observation. It occurred in a man who had received a severe beating, and, among the results, loss of vision began after about six weeks. He examined him, and found anæsthesia of the fifth nerve, the hearing involved, and several small retinal hæmorrhages around the point of entrance of the optic nerve.

Empyema.—Dr. Chew had been called in consultation to a patient who for several days had suffered from severe dyspnœa. The night before he saw him he had had copious expectoration of matter, the nature of which he could not describe, as it was not saved. This was followed by immediate relief from the difficulty of respiration. Upon physical examination of the chest, the left pleura was found to be about two thirds filled with fluid. Shortly after his visit the patient suddenly died with profuse vomiting of purulent matter, as well as the passage of quantities of it from the bowels. From such symptoms he thought it highly probable that perforation took place through the diaphragm into the stomach, and that the fluid was discharged both through the œsophagus and through the intestines. He had searched the literature on the subject and had found no record of a case terminating in this manner. Physical examination of the chest made before the first expectoration of matter showed the pleural cavity to be entirely filled with fluid. More recently he had seen a patient at the Baltimore Infirmary whose physiognomy was indicative of pulmonary trouble. Percussion over the right side of the chest gave decided resonance, both anteriorly and posteriorly. On ausculation on the same side, there was pronounced Hippocratic succussion. No discomfort at all was noticed, neither pain nor dyspnœa. He thought the absence of dyspnœa could be explained on the ground that the air probably distended the pleura (and this compressed the lung) so gradually that this lung, as well as the healthy one, had sufficient time to accustom itself to its abnormal relations. Whether perforation was due to ulceration outward through the pleura from the wall of a cavity in the lung, or whether it was due to a loss of substance occasioned by a point of inflammation upon the visceral pleura, thus perforation taking place in the reverse direction, he could not say, although symptoms sufficiently marked were present to point to either mode. In his opinion, surgical interference should be resorted to as soon as the condition of empyema was made out.

Dr. Arnold had seen a case of empyema in a child, which occurred on the right side, ulcerated through the diaphragm, and discharged its contents into the abdominal cavity. The child died from shock. He considered it somewhat remarkable how rarely phthisical patients showed any signs of discomfort from interference with respiration, even though their lungs might be riddled with cavities.

Dr. Chew looked upon this as due to the slowness of the pathological process, this enabling that portion of the lung which was healthy to increase its physiological activity. He also thought, in view of the fact that cavities so frequently formed near the pleura, that it was singular that we so rarely found perforations from them.

The President said serous sacs resisted perforation.

The Cocaine Habit.—Dr. J. C. Thomas said that since he had been told that in some of our principal cities the cocaine habit was largely being acquired, he would like to ask if any member had ever seen a case of it, and, if the report was true, whether the medical profession should not take steps to prevent the reckless prescription of this seductive drug.

The President related two cases in which decided loquacity had been produced by the introduction of cocaine into a cavity in a decayed tooth. In speaking of *cocaine tablets*, he referred to a condition, amounting almost to a slough, that was produced on the buccal surface of his own cheek from the application of one of these tablets to the gum and allowing it to remain until dissolved. From this, he hardly considered them the proper thing to use in nasal catarrh.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

The Sensitiveness of the Normal Eye to Differences in the Wave-Lengths of Light.—König and Dieterici ("Arch. f. Ophth.") conclude, from their investigations upon this subject: 1. The differences in color-sensibility at the red end of the spectrum, as far as the line C of the spectrum, are dependent solely upon the existing differences of intensity. 2. The maximum sensitiveness for differences in wave-length in the yellow region of the spectrum lies for the two observers at different points of the spectrum. 3. The two other maximum conditions (in the blue-green region and the region of fusion of indigo and violet) lie, with the same or equal intensity, at the same point for both observers. 4. But they pass with increasing intensity toward the violet end of the spectrum just as the neutral point in the spectrum of those who suffer from red-green blindness.

Investigations into the Light-Sense and the Sense of Space in Different Diseases of the Eyes.—Bjerrum (*Ibid.*) gives the results of his laborious investigations upon the light-sense and sense of space in connection with various diseases of the eye as follows: 1. Among patients with the same acuity of vision for black on white by good illumination, one individual may show a markedly abnormal diminution of vision by lowered illumination (hemeralopia), but good vision by diminishing differences of brightness and by unchanged illumination; while another individual may show good vision by diminishing illumination, but bad vision by diminishing differences of brightness. 2. Among individuals with the same acuity of vision one may show marked hemeralopia, but a perfectly unaltered sensitiveness for differences of brightness by good illumination on a white Masson's disc; another may, on the contrary, show no hemeralopia, or a very slight degree of it, but a very considerably diminished sensitiveness for differences of brightness under the same conditions. 3. The light-sense may be so affected in the central part of the retina in one individual that the limit of irritability is displaced upward, while the limit of difference under a greater absolute brightness is not affected, while in another individual the reverse will be the case. 4. The investigations showed that persons with affections

of the retina and choroid showed a particular tendency toward hemeralopia, while patients with atrophy of the optic nerve showed a tendency to diminution of sensitiveness for differences of brightness under a greater absolute brightness. The examination of cases of congenital and strabismic amblyopia revealed nothing. The cases of central amblyopia resembled in this regard those of optic-nerve atrophy. 5. The so-called nyctalopia as a rule depends upon the circumstance that many cases of amblyopia, when the illumination diminishes, approximate more and more the normal, both as regards the sense of space and the light-sense.

Researches into the Perception of the Differences of Brightness or Illumination.—Charpentier ("Arch. d'ophth.") formulates the results of his investigations as follows: 1. The perception of differences of brightness is always influenced by the illumination. 2. The differential fraction diminishes continuously as the illumination increases. 3. There is no simple law which can explain the relation between the illumination and the value of the differential fraction, but an approximative law would be as follows: the differential fraction varies inversely as the square root of the illumination. 4. The perception of differences of brightness varies according to the size of the objects to be distinguished. 5. The differential fraction diminishes continuously as the size of the object increases.

Rare Tumor of the Orbit.—Story ("Ophth. Rev.") reports an interesting case of orbital tumor occurring in a young girl who had never suffered from any inflammation or painful affection of the eyes or orbits. As long as could be remembered there had been noticed a small lump beneath the left lower eyelid toward the nasal side. This lump became more prominent at certain times, and slightly discolored, and this was especially noticeable when she laughed or cried, or after stooping or taking violent exercise. On palpation, a hard body of about the size of a small pea could be felt beneath the discolored skin, and was freely movable in all directions in the orbital cavity. It could be drawn forward and made to project through the fornix beneath the eyeball. On dividing the skin and fascia over it, the tumor projected through the opening, inclosed in a thin but firm capsule. On dividing this capsule, the tumor popped out upon the cheek, there being no pedicle. It was nearly spherical, being one centimetre long and seven millimetres broad, and at one extremity of the longer diameter a smaller spherical tumor, about two millimetres in diameter, was firmly attached to the primary one. On making a section with a saw, the tumor was seen to be formed of a series of concentric lamellæ, the peripheral layer resembling bone in appearance. A microscopical examination, however, showed no bone, but only a series of different layers of fibrous tissue and calcified matter.

Chronic Tuberculosis of the Eye.—Schäfer ("Klin. Monatsbl. f. Augenheilk.") gives the results of an examination of an eye removed, for general intra-ocular inflammation and exophthalmus, from a soldier of healthy constitution. The eyeball was 29 mm. long and 21 mm. wide, and almost shapeless. The cornea was 3 mm. thick; the sclera varied in thickness from 1½ mm. to ¾ mm. The anterior chamber was very shallow, and filled with a granular, dark-yellow mass. Two millimetres external to the corneal margin was a narrow, funnel-shaped, gaping cleft leading into the interior of the eye. This opening was surrounded by a broken-down, grayish-yellow mass similar to that in the anterior chamber. This extra-ocular tumor was connected by this cleft with the intra-ocular tumor, and section showed that it originated in the outer or temporal half of the choroid behind the ciliary body. The microscope showed a lymphoid infiltration of the entire uveal tract, which in places formed conglomerate nodules or masses. The lens and capsule were involved in the same degeneration, and everywhere there was partial necrosis of the original and neoplastic tissues, with caseous metamorphosis and granular detritus. There was also in places developed a dense, vascular granulation tissue with numerous similar nodules imbedded in it. The tubercle bacillus was carefully searched for, but not found.

A Portable Campimeter.—Gazepy ("Rec. d'ophthal.") describes a portable apparatus for measuring the field of vision, which consists of three principal parts: 1. A central black disc, 5 ctm. in diameter, furnished with three claws, by which it may be attached to the wall or blackboard. This disc is divided into twelve parts: in the center is the white point of fixation, 15 mm. in diameter; it is mounted on a pivot, and is attached by an index which, turning on its axis, shows the degrees of inclination. 2. A metallic ribbon connecting it with a second disc. This ribbon is 5 mm. wide and 50 ctm. long. On one side are marked off divisions in centimetres, and on the other the tangent of the angles. The second, or peripheral disc, is of the same size as the first, and is composed of two parts: a plate turning on its axis and divided into five equal peripheral segments of the fundamental colors —red, blue, green, yellow, and white. These colors are to be used in cases where it is necessary for the chromatic perception of the visual field. Upon this first disc or plate there is superimposed a second disc revolving on the first, and forming a diaphragm, by which the quantity of colored surface which is to be examined may be varied. This disc contains five holes: the first is of the size of a common segment of the two discs; the second is 14 mm. in diameter; the third is 10 mm.; the fourth is 5 mm.; and the fifth is 3 mm. At the periphery of this disc is attached a small metallic box, 33 mm. in diameter, which is destined to receive the ribbon which unites the two discs; there is also attached to the box an apparatus for fixing the ribbon. The central disc is to be affixed to the wall or blackboard, and the patient's head is placed at 16 ctm. from the point of fixation; the peripheral disc is then removed as far as the unrolling of the ribbon will allow; then, in order to determine the point where the patient sees the peripheral white point distinctly, the second disc may be brought nearer the first by shortening the ribbon. This manœuvre is possible for all meridians, it being only necessary to turn the index which indicates the degress of inclination.

Traumatic Dyschromatopsia.—Armigo (*Ibid.*) reports a case of this kind in an officer who was wounded by a rifle-ball on the left side of the head, the auricle being carried away and the temporal bone fractured. He was unconscious for several days and was slightly delirious. When consciousness returned, it was found that he had entirely lost his memory. He was very deaf, and the senses of smell and taste were destroyed. He could not distinguish any colors, everything appearing either black or white. There was no paralysis of any muscle of the eye, nor of any in the body, but he said that in walking he felt as if he had only the left side of his body. The hearing returned in the left ear (the wounded side), but not in the right ear. Taste and smell also returned slowly. Two years later the dyschromatopsia began slowly to disappear, red being the first color recognized and green the last.

The Treatment of Granular Ophthalmia.—Vouckchevitch (*Ibid.*) draws the following conclusions in favor of excising the conjunctival *cul-de-sac*, as the only radical means of cure: 1. No specific remedy has ever been discovered for palpebral granulations. 2. Caustics, astringents, and antiseptics, as hitherto employed, are insufficient to heal granulations. 3. The inoculation of pus may be employed with prudence in certain specific and restricted cases. 4. Jequirity has not been sufficiently studied as yet to be accorded all the therapeutic value attributed to it. 5. All the methods of treatment hitherto mentioned seem rather to heal the complications of granulations than the granulations themselves. 6. The abrasion of the granulations made by Heisrath and others may cause serious deformity of the lids. 7. The granulations of the *culs-de-sac* are very difficult to reach by ordinary caustics, by reason of their situation and the anatomical relations of the lid with the eyeball. 8. The excision of the *cul-de-sac* heals very old granulations. 9. This excision causes no serious deformity of the lid, and is an operation very easily performed.

The Anatomy and Pathology of Retinitis Pigmentosa.—Guaita (*Ibid.*) draws the following conclusions in regard to the nature of retinitis pigmentosa: The morbid process is here a peripheral, progressive, centripetal angio-sclerosis of the retina. The first alteration observed consists in the concentric hypertrophy of the capillary walls of the retina, which extends at first to the entire capillary system of the equatorial region. As a result, the filtration of the nutritive plasma is hindered, and hence follow grave disorders in the current of the nutritive fluids circulating in the interstices of the retina. Owing to this sclerosis of the retinal capillaries, the current of the plasma which comes from the central branches of the optic nerve is at first diminished and afterward suppressed. The choroidal current should aid by collateral circulation, but does not replace the absence of the retinal vessels. The process of hyperplasia of the connective tissue increases and ex-

tends to the larger vascular branches and to the connective-tissue framework of the retina. This aids in destroying the retina by compressing those elements which still survive. It advances slowly and ends by attacking the largest vessels and the interstitial connective-tissue of the retina and optic nerve. The retiua is thus transformed into a connective-tissue membrane crossed by fibrous cords which arc covered by masses of pigment cells.

The Relations between Ocular Symptoms and Dental Lesions.—Power (*Ibid.*) classifies as follows the phenomena which may appear in the eye in connection with certain morbid conditions of the teeth: 1. Phenomena of reflex irritation which affect striated or non-striated muscular fibers. 2. Phenomena of reflex irritation which affect the mucous membrane and the cornea. 3. Reflex irritation affecting the optic nerve and retina, or the intra-ocular tissues. In the first class we put paralysis of the ciliary muscle, paralysis of the intra-orbital muscle, paralysis of the iris, paralysis of one of the muscles of the eyeball, and paralysis of the orbicular muscle of the eyelids.

Lesions of the Trifacial Nerve in Locomotor Ataxia.—Galezowski (*Ibid.*) continues his series of remarks upon ocular lesions in connection with locomotor ataxia, and this time takes up the lesions of the fifth nerve. He finds that they may occur at all periods of ataxy, though they are more common in the early stage. Sometimes there is a sort of hyperæsthesia disseminated all over the circum-orbital region, especially on one side, accompanied by very severe intermittent pain. These patches of hyperæsthesia all lie along the course of the branches of the fifth nerve. The lancinating pains may be propagated to the eyeball, which becomes the seat of a veritable neuralgia. Sometimes patches of anæsthesia are met with, which, however, only appear after severe pain, and are in a sense transformations from hyperæsthesia. These anæsthetic patches are also situated along the branches of the fifth nerve, the insensibility coming on gradually and sometimes becoming absolute. The local treatment should consist especially in the employment of revulsives, chiefly blisters. The continuous galvanic current, applied directly to the particular branch or branches affected, sometimes renders good service. In some cases methodical hydrotherapeutics gives good results. Galezowski also speaks well of the "mixed" mercurial treatmeut, combined with mercurial inunction. He has also employed hypodermic injections of the cyanide of mercury, making a solution of 3 grains of the cyanide in 2½ drachms of water, and injecting every day from five to ten drops. In the general treatment of ocular lesions of whatever nature, occurring in the course of ataxy, Galezowski also recommends as a hypodermic injection a solution of cyanide of gold and potassium, and also the bromide of gold and potassium, the latter being not so acid as the former.

Clinical and Pathogenetic Connection between Detachment of the Retina, Myopia, and Glaucoma.—Drausart ("Ann. d'ocul.") has been investigating this subject in connection with the operative treatment by iridectomy and sclerotomy, and draws the following conclusions: 1. There are clinical and pathogenetic relations between glaucoma, detachment of the retina, and myopia which seem incontestable. These relations may possibly explain the beneficial effect of iridectomy on detachment of the retina. 2. If iridectomy, in connection with the use of pilocarpine and the horizontal position, is regarded as the best method of treatment for detachment of the retina, on the other hand, sclerotomy, iridectomy, and all the therapeutical agents opposed to excess of tension, and employed in progressive myopia, must be regarded as most powerful adjuvants in the prophylactic treatment.

Astigmatic Keratitis.—Martin (*Ibid.*) continues his previous discussion of this subject in a fourth paper, and formulates two statements as follows: 1. Congenital astigmatism is often, but not always, accompanied by a flattening of the eyeball. 2. In half the cases, the spots upon the cornea produced by a keratitis coincide with a flattening of the organ. His final conclusions are as follows: 1. Cases of corneal spots without astigmatism are rare. 2. The degrees of astigmatism grouped round each patient are much greater than those observed in an equal number of patients who have never shown any ocular lesion. 3. Muscular spasm varies in importance in different affections. 4. In many cases where astigmatism has been discovered it exists in connection with hypermetropia, as in scrofulous keratitis, where more than half the patients examined were hypermetropic. In these cases the hypermetropia is no doubt partially the cause, as well as the astigmatism.

Glaucoma produced by Homatropine.—Sachs ("Centralbl. f. prakt. Augenheilk.") reports a case of acute glaucoma produced by the instillation of homatropine. The patient was a man, aged fifty-eight, who came to the clinic desiring to be measured for a pair of reading-glasses. He had never seen well at a distance. Both eyes showed a shallow anterior chamber with normal tension and normal pupils. One drop of a one-per-cent. solution of homatropine was instilled, and, after mydriasis had been produced, it was found that the lens in each eye showed a zone of punctate opacities between the nucleus and the anterior capsule. There was no disease in the fundus, and the visual field and color-sense were normal. The next day the patient came with the complaint that, shortly after having left the clinic the day before, he had been attacked with pain in the temple and forehead, marked disturbance of vision, and vertigo, and that these symptoms had continued. The right eye showed a typical picture of a moderate acute glaucoma; cloudy cornea, punctate epithelium, very shallow anterior chamber, pupil dilated to 5·5 mm. and immovable; arterial pulsation on the disc; increased tension; vision reduced to the power to count figures at three metres; limitation of the field on the temporal side. Eserine was immediately instilled several times, and in an hour all signs of glaucoma had vanished.

The Pathological Anatomy of Primary Sarcoma of the Iris.—Thalberg ("Arch. of Ophth.") gives the results of his examination of the eyeball of a woman, aged sixty-four, which had been enucleated for irido-cyclitis dolens. The development of the neoplasm from the endothelium of the iris could be distinctly traced at the place where the corneal tumor passed over upon the anterior surface of the iris. The development of this sarcomatous neoplasm seemed apparently the result of a cataract extraction. From its origin in the endothelium, and from the form and size of the cells, it was evidently a sarcoma, and of the round-cell variety. In the peripheral (most recently formed) portion the tumor had the appearance of a simple granuloma. In the central (oldest) portion there was a rather sudden transition from these small cells into large polygonal and round sarcoma cells; among them were some large spindle cells. By division of the large polygonal cells, small ones were formed, which at first retained their polygonal form, but, by further division, passed over into round cells as large as lymph cells. The cornea was considerably thickened and infiltrated, and blood-vessels ran from it into the tumor. The growth filled the anterior chamber, formed a vascular connection with the cornea, and passed through the opening in the center of the capsule into the vitreous; but it did not enter the iris tissue proper.

The Comparative Frequency of Eye Diseases in the White and Colored Races in the United States.—Burnett (*Ibid.*) has been investigating this subject with some care, and has made a very interesting article. Taking *conjunctival diseases* as a whole, he finds that they are of about the same relative frequency in the two races. *Scrofulous conjunctivitis*, including herpes of the conjunctiva, sclera, and cornea, is very much more frequent in the colored race. When we come to *trachoma*, Burnett has never seen a genuine case in the negro race, even among the mulattoes. He thinks that the trachoma granule, follicle, or whatever name we may give it, is a deposit of material analogous in character to tubercle. At least they both seem to have this in common, that when they disappear the tissue in which they were imbedded is destroyed, and a cicatrix is the result. There is another similarity in the successive crops of these deposits which may occur. He thinks each fresh attack of trachomatous inflammation is the manifestation of a fresh deposit, and, where there is a series of them in a number of years with these resultant cicatrices, we see that total destruction of the mucous membrane so commonly met with in old cases. As regards diseases of the cornea, we find in the negro a disproportionately large number of inflammations of all kinds. When we come to iritis, the percentage among the negroes is twice that among the whites, though the percentage of syphilitic iritis in the negroes is not greater than among the whites. From his own experience, Burnett thinks that, other things being equal, the negro offers as good a general prognosis in eye operations as the white race, though the former is rather more liable to reactions on the part of the iris after extractions.

The Indications and Contra-indications of Jequirity.—De Wecker

(*Ibid.*), in a second communication on this subject, affirms that there is never any purulent secretion so long as the jequirity ophthalmia lasts; a thin watery discharge trickles down over the cheeks, while a whitish, viscid substance covers the edge of the lids. Jequirity does not produce a purulent, but a croupous or croupo-diphtheroid ophthalmia—croupous, if the remedy is only applied superficially; croupo-diphtheroid, if an intense action has been produced by rubbing or the application of strong infusions. No danger attends the careful single or even repeated application of a three-per-cent. infusion to a normal, non-secreting conjunctiva. The jequirity ophthalmia produces the least amount of scar-tissue, and favorably affects that which has previously existed.

Further Observations on the use of Jequirity.—Knapp (*Ibid.*) has another brief communication upon the use of jequirity in ophthalmic practice. He thinks that the occurrence of diphtheria, and occasionally diphtheritic inflammation of the most deleterious kind, must be registered as one of the possible consequences of the application of jequirity infusion. In cases of inveterate, dense pannus with advanced cicatrization of the conjunctiva, the remedy is incapable of producing diphtheritic infiltration or purulent discharge to any great extent, for the cicatricial tissue, very scantily supplied with blood-vessels, can not furnish nutritive material enough for either an infiltration into the depth of the conjunctiva or an abundant purulent secretion.

New Formation of the Epithelium of the Anterior Capsule of the Lens in Adult Animals in Conditions of Health and Disease.—Falchi ("Arch. f. Ophth.") has been making some investigations into the frequency of indirect cell-division in the epithelium of the anterior lenticular capsule, and concludes as follows: 1. In the normal state this process is much rarer among mammalia and birds than among amphibia. 2. In adult rabbits, after a wound of the central portion of the anterior capsule, the indirect cell-division of the anterior capsular epithelium occurs most frequently in the neighborhood of the wound; at a certain distance from the wound the process is but rarely met with; and at points very distant from the wound it is never seen. Even in the vicinity of the wound the number of cells involved in the process was never large, and they were generally isolated, not conglomerate.

A Light-reflex from the Retina.—Heuse (*Ibid.*) calls attention to an appearance, hitherto undescribed, which may be seen with the ophthalmoscope in the upright image. It consists of a narrow, oval ring of light on the retina, which changes its shape according to the position and property of the illuminated spot. If it strikes a wide retinal vessel, the ring is changed into the shape of a heart; sometimes a portion of the ring passes into a broad, diffuse, shining streak; sometimes two faint rings are seen, the one included within the other. In two instances Heuse saw, at the spot where the ring was, a distinct, pale, inverted image of the candle-flame. The ring is best seen when the observer is very close to the eye observed. Reflected figures of a similar shape may often be seen at the bottom of vase-like vessels which are homogeneously illuminated. He regards this ring as a reflex from the walls of the interior of the eye. He assumes a double reflection within the shell of the retina in such a way that from the first reflex image, which is subjectively perceived, there results a second reflection toward the source of the original reflection. This reflex can not be seen in all emmetropic and hypermetropic eyes. It may be found in about one third of children's eyes, and is rarer in older persons.

Glaucoma.—Jacobson (*Ibid.*) has a long and interesting paper, which is mainly devoted to the relations existing between acute and chronic glaucomatous attacks, and to the causation of both. He thinks that the diagnosis of chronic glaucoma can not be made independent of the appearance of the so-called glaucomatous or marginal excavation. This excavation is rather to be regarded as a late stage of the process. The diagnosis of chronic glaucoma may be made from every excavation of the optic disc in connection with the subjective symptoms of periodic obscuration of sight and rainbow vision, and the objective symptom of constant increase of tension. Failure of vision, periodical headaches, indefinite states of tension, are all of secondary diagnostic value. By the spreading out or extension of the vitreous, every point of the ocular surface suffers an equal pressure. The yielding portions of the optic disc give way to this pressure more than any other parts of the eye, while, in the anterior part of the eye, the lens, zonula, ciliary processes, and iris also give way. As soon as the periphery of the iris is pressed against the cornea, Fontana's space is closed; and, as soon as this position becomes fixed by adhesion or by a permanent change in the vitreous, the exit of lymph ceases to a great extent, and this leads to glaucomatous degeneration. Jacobson draws the following conclusions from his observations: 1. The disturbance of central and peripheral vision in chronic glaucoma may be explained by the excavation of the optic disc; this is the pressure-excavation. 2. The marginal excavation is a late symptom, which is preceded by a shifting of the vessels at first backward in the vicinity of the central canal, and afterward on the margin of the excavation. 3. The prodromal stage of chronic glaucoma is characterized by four symptoms: subjective obscurations, excavation of the central canal, dilatation of the pupil, and increased tension. 4. Iridectomy is of most avail in the prodromal stage. 5. Among the causes of the prodromal stage are the accommodative strain of hypermetropes on account of the venous stasis which follows prolonged muscular contraction. 5. The glaucomatous eyeball maintains its hardness longer after enucleation than the normal eyeball. 7. The cause of the hardness is the increase in volume of the vitreous. 8. The hypertrophied vitreous spreads backward toward the central canal of the optic nerve; forward toward the space between the lens and the ciliary processes; it presses the latter against the origin of the iris, the latter against the cornea, and closes Fontana's spaces. Sometimes the vitreous may even alone obstruct the exit of the lymph. 9. The clouding of the media in acute glaucoma and in the prodromal stage is due to an œdema and not to an inflammatory product. 10. The obscurations of the prodromal stage without clouding of the media point to an extended circulatory disturbance as cause, such as venous stasis or arterial anæmia. 11. In the increased amount of the vitreous humor we have a lasting cause for further venous stasis and œdematous and inflammatory infiltrations. 12. The transition from acute to chronic glaucoma is explained directly by the increase in tension; the transition from chronic to acute glaucoma may, perhaps, be explained by the venous hyperæmia in the anterior half of the eyeball, in consequence of the increase in volume of the vitreous.

Jequirity Ophthalmia.—Wecker (*Ibid.*) again enters upon the discussion of this subject in a critical answer to von Hippel's recent paper. He starts with the axiom that the intensity of action of the drug increases with the strength of the infusion. He then states that the more the conjunctiva swells and the more evident the signs of acute or chronic purulent ophthalmia appear, the more difficult it is to produce the specific jequirity ophthalmia with its croupo-diphtheroid exudation, and hence the less reliance can be placed upon its action. Further, the more the trachomatous condition is complicated by papillary swelling, hyperæmia, and increased secretion, the more difficult it is to produce the croupo-diphtheroid jequirity ophthalmia. He is firmly convinced that true granulations and trachoma are cured by jequirity, but that false granulations or the papillary hypertrophy of chronic purulent ophthalmia are rather made worse by its use. The duration of the stage of incubation varies with the looseness or tightness of the eyelids, which allow more or less air to pass into and over the conjunctiva which has been bathed with the infusion.

A Case of Traumatic Pulsating Exophthalmos partially cured by Ligation of the Common Carotid, and entirely cured by Extirpation of the Aneurysmal Varix of the Orbit.—Knapp ("Arch. f. Augenheilk.") reports a case of this kind occurring in a woman aged forty-eight. Seven years previously she had received a blow on the left temple, from which she was unconscious for several days. The blow produced complete and permanent paralysis of the left side of the face. The left eye became at once prominent, but was reduced; the lids could not be closed, and in a few months she began to hear a pulsating noise in the left side of the head. This gradually increased in intensity and annoyed her extremely. After a year the blood-vessels of the lids began to swell and the eye became prominent. From this time all the signs of a pulsating tumor in the orbit became very marked. The left common carotid was ligated on November 29, 1880, and immediately after the operation a weak systolic murmur was audible, and forty-eight hours later a weak pulsation could be felt in the vessels above the orbit. In the course of the year the enlarged blood-vessels of the face gradually subsided, but there was no change in the exophthalmos, which slowly increased. On October 12, 1882, the eye was enucleated

and then the tumor carefully extirpated, and the entire contents of the orbit were removed. This operation resulted in a complete and radical cure. Knapp thinks that the period from the time of the injury to the appearance of the exophthalmos was longer than usual, and it is probable that the injury consisted of an inconsiderable laceration of the carotid, which resulted in a communication between the artery and the cavernous sinus. The chief mass of the recurrent tumor in the orbit was an aneurysmal varix, while the smaller tumor met with in the extirpation was a pulsating cavernoma. The very large blood-vessel which was divided at the bottom of the orbit was the superior ophthalmic veiu. In explanation of the manner in which the extirpation of the entire contents of the orbit brought about the cure of the communication with the cavernous siuus, Knapp assumes that the sudden obliteration of the orbital veins caused a thrombus in the cavernous sinus, which proceeded from the mouth of the ophthalmic vein, but extended so far into the sinus as to cover the laceration in the carotid.

A Case of Sudden Amaurosis with Subsequent Hemianopsia Homonyma Superior.—Wiethe (*Ibid.*) reports a case of this nature in a man aged fifty-four. Two years before the patient had had acute articular rheumatism with cardiac complication. Five months before Wiethe saw him he had fallen from a ladder a distance of three metres and struck on the back of his head. There was bleeding from mouth, nose, and ears, and he was unconscious for several hours. The following Easter apoplexy and left hemiplegia supervened, but in a few weeks he recovered completely. The day before Wiethe saw him his vision suddenly became clouded, and in an hour and a half he was entirely blind. The pupils were dilated *ad maximum* and immovable. The eyeballs were immovable with parallel axes. Ophthalmoscopically, nothing abnormal was discovered. The patient complained of violent headache. Two days later the left pupil grew narrower and reacted to light, and the patient saw a faint cloud, and later in the day could count fingers with the left eye at fifteen feet and with the right eye at twelve feet. On the fifth day the headache had disappeared and the pupils were of normal size and reaction. Some days later the patient could count fingers at eighteen feet, and the color sense was normal. There was an apparent hemiopia of both eyes upward, on testing the field of vision. A diagnosis was made of hæmorrhage at the base of the brain in the neighborhood of the optic chiasm. The patient lived for nine months and a half, and died of strangulated hernia. At the autopsy there were found atheroma of the arteries at the base of the brain, and old apoplectic foci in the left parietal lobe and left temporal lobe, in the left optic thalamus and left lenticular nucleus, and also in the medulla of the right frontal lobe, and the cortex of the right sulcus olfactorius was the seat of chronic pachymeningitis. There was not a trace of any hæmorrhage in the vicinity of the chiasm, optic nerves, or optic tracts, nor of any fracture of the skull.

Stretching of the External Nasal Nerve in Neuralgia of the Ciliary and Trifacial Nerves.—Lagrange ("Arch. d'ophthal.") draws the following conclusions from his own observation and experience: 1. Stretching of the external nasal nerve acts beneficially on ciliary neuralgia. 2. The pain can be cured in every case without reference to visual troubles resulting from grave lesions of the deep structures of the eyeball. 3. This special effect produced by stretching the external nasal nerve may be explained by the relations of this nerve-trunk to the ophthalmic ganglion. 4. The stretching may act in two ways: either by reflex action or by the production of an actual solution of continuity between the sensitive root of the ophthalmic and the trunk of the nasal nerve. 5. In neuralgia of the trigeminus, stretching of the external nasal nerve is of no special value.

Miscellany.

A Reminiscence of the Civil War.—Under the title of "A Ride with Sheridan," Dr. A. D. Rockwell gives a very interesting account of a portion of his campaigning experience, in a recent number of the "Magazine of American History." The following passage from Dr. Rockwell's article vividly sets forth one of the aspects of an army surgeon's life:

And here, without any invidious distinction, attention may be called to the work of the medical staff of the army, who labored without hope of special preferment or possibility of distinction. They shared the fatigue and much of the danger of the campaign, and in emergencies their labors were simply incredible. On this very march, for instance, after a long day's ride, when all others were sleeping, the surgeons collected about the ambulances, and, with the dim light of candles, dressed each wound with gentle care. Every effort was made to save the lives of those who were not too far gone. The dying were passed by, excepting to minister to their immediate wants, and the dead were quickly buried. As I recall, at this distance of time, those nights of toil, with wagons against the dark background crowded with wounded, and surgeons here and there bent low over the sufferers, engaged in their humane ministrations, the scene loses none of its weird and solemn impressiveness. We passed over the recent battle-field of Spottsylvauia, where the destructive effects of the terrific shower of shot and shell were plainly visible. Broken branches of trees were on every haud. Many trees were almost completely denuded of bark and foliage, some were riddled with bullets, and others were felled to the ground by the shots. Brigadier-General Grant, of the Vermont Brigade, Sixth Corps, thus graphically describes the close and deadly fighting at the celebrated "Angle": "It was not only a desperate struggle, but it was literally a hand-to-hand fight. Nothing but the piled-up logs or breastworks separated the combatants. Our men would reach over the logs and fire into the faces of the enemy, would stab over with their bayonets, and many were shot and stabbed through the crevices and holes between the logs. Men mounted the works, and, with muskets rapidly handed them, kept up a continuous fire until they were shot down, when others would take their places and continue their deadly work. . . . Several times during the day the enemy would show a white flag about the works, and, when our fire slackened, jump over and surrender, and others were crowded down to fill their places. . . . It was there that the somewhat celebrated tree was cut off by bullets; there that the brush and logs were cut to pieces and whipped into basket stuff; . . . there that the enemy's ditches and cross-sections were filled with dead men, several deep. . . . I was at the 'Angle' the next day. The sight was terrible and sickening, much worse than at Bloody Lane (Antietam). There a great many dead men were lying in the road and across the rails of the torn-down fences, and out in the corn-field, but they were not piled up several deep, and their flesh was not so torn and mangled as at the 'Angle.'"

The New York Academy of Medicine.—A Section in Laryngology and Rhinology will be organized on Wednesday evening, the 23d inst., and Dr. R. P. Lincoln will read a paper entitled "The Surgical Uses of Electricity in the Upper Air-Passages." The Section in Obstetrics and Diseases of Women and Children will meet the same evening, and Dr. Egbert H. Grandin will read a paper entitled "An Obscure Case of Abdominal Gestation, with Remarks bearing particularly on Timely Diagnosis and Treatment." Notice is given that neither the paper nor the discussion is intended to cover the subjects of tubal and interstitial gestation. The Section in Ophthalmology and Otology will hold a meeting on Monday evening, the 21st inst. A paper on "Contrast of Colors" will be read by Professor Ogden N. Rood, of Columbia College, and one on "Antiseptics in Eye Surgery" by Dr. Henry D. Noyes.

A Jewish View of the Operation of Craniotomy.—In the "American Israelite," Dr. M. Mieiziner, of Cincinnati, says that in Mishna *Oholoth*, vii. 6, the undisputed decision is laid down that "in case of a dangerous parturition it is justifiable to kill the unborn infant in order to save the mother, as her life precedes its life." Such operation is, however, not permitted after the infant has already been partially born, as in the latter case the maxim applies, one human life must not be set aside on account of another. In his commentary on Talm. Sanhedrin 72*b*, where this Mishna is quoted, Rashi explains the reason of the distinction between these two cases to be that the unborn infant is not yet a *distinct personality* with an *independent* life; hence the duty of saving the mother's life is to prevail, while in the second case its individuality is established; hence the legal principle must apply that one life must

not be destroyed to save another. The authoritative codes of Maimonides (Hilchoth Rotzeach u Shemirath Nephesh I. 9), as well as of R. Joseph Caro (Choshen Mishpat 425. 2), adopted the decision of the Mishna as the rule of Jewish law.

The Health of Chicago.—According to the Health Department's "Condensed Statement of Mortality," the deaths in November included 1 from small-pox, 36 from scarlet fever, 79 from diphtheria, 39 from croup, 6 from whooping-cough, 1 from typhus, 39 from typhoid fever, 5 from cerebro-spinal fever, 8 from malarial fever, 15 from other zymotic diseases, 7 from diarrhœal diseases, 103 from pulmonary phthisis, and 82 from acute lung diseases.

Bromidia.—Dr. Thomas Stretch Dowse, of London, in a letter to the manufacturers of this preparation, says: "I am glad to speak in praise of your preparation named bromidia. As it is a known compound in quantity and quality, its virtue should be known, and not even the most fastidious of physicians can refuse to prescribe it. I have found it a most valuable hypnotic and sedative, and it unquestionably controls the circulation of the brain generally, and the nervous centers and gray matter in particular. In muscular spasm and in epilepsy its effect is very marked."

The late Mr. Vanderbilt.—At a special meeting of the Faculty of the College of Physicians and Surgeons, the Medical Department of Columbia College, in the City of New York, held on December 10, 1885, the following preamble and resolutions were unanimously adopted:

Whereas, By the death of William H. Vanderbilt there has been taken from the community a citizen from whose hands the college has received a splendid addition to its means of usefulness, be it

Resolved, That we offer hereby our tribute of mourning for the loss of a benefactor whose service to the advancement of education has been great and enduring—as broad in scope as free in gift—and whose enlightened generosity will ever be held in grateful remembrance by ourselves and our successors.

Resolved, That we tender our heartfelt sympathy to the family of the deceased in their bereavement.

Resolved, That, as a token of respect, all exercises at this college be suspended on the day of the funeral, and that we attend the same in a body.

Resolved, That these resolutions be communicated to the family, and be duly published.

[Signed] John G. Curtis, M. D.,
Secretary of the Faculty.

Errata.—Dr. William A. Hammond, whose article on Unilateral, Hallucinations we published last week, informs us that we were in error in attributing to him the possession of the degree of LL. D.

In the article by Dr. Bacon and Dr. Roosa, in the same issue of the Journal, page 659, for "Dr. William T. White" read *Dr. W. H. White.*

THERAPEUTICAL NOTES.

The Physiological Action of Tobacco.—In the Fiske Fund Prize Dissertation, No. XXXIV, entitled "The Physiological and Pathological Effects of the Use of Tobacco," recently published by Messrs. P. Blakiston, Son, & Co., of Philadelphia, the author, Dr. Hobart Amory Hare, presents the facts and arguments that have led him to the following conclusions:

1. Tobacco smoking does not decrease the urine eliminated, but rather increases it. 2. Tobacco does retard tissue waste. 3. Tobacco and its alkaloid cause convulsions in the primary stage of the poisoning, by depressing the reflex inhibitory centers in the cord. 4. It causes the palsy of the second stage, by paralyzing (*a*) the motor nerve trunks, (*b*) the motor tract of the spinal cord. 5. The sensory nerves are not affected by the drug. 6. Nicotine contracts the pupil, by stimulating the oculo-motor and paralyzing the sympathetic, this action being peripheral. 7. Nicotine primarily lowers the blood-pressure and pulse-rate; (*a*) secondarily increases pressure and rate; (*b*) thirdly, decreases pressure. 8. The primary lowering of pressure and rate is due to pneumogastric stimulation, associated with vaso-motor dilatation. 9. The secondary stage is due to vaso-motor constriction and pneumogastric palsy. 10. The third stage is due to vaso-motor dilatation returning. 11. Death in poisoning from this drug is due to failure of respiration, the action of the drug being centric. 12. The blood-corpuscles are broken up and crenated by the action of the poison. 13. In death from nicotine poisoning the blood shows changes in *spectra*. 14. Death can be brought about by the cutaneous absorption of nicotine. 15. Tobacco increases intestinal peristalsis in moderate amounts, and produces tetanoid intestinal spasms in poisonous doses. 16. The liver seems to destroy the poison, although this destruction is participated in by any set of capillaries in other parts of the body. 17. Tobacco smoking increases the pulse-rate and decreases arterial pressure.

Hypnone as a Hypnotic.—The fanciful name hypnone has been applied to methylphenylacetone. At the request of M. Dujardin-Beaumetz, who insists that it should be used only in cases of sleeplessness from over-excitement of the brain, and not where there is pain, M. Pierre Vigier ("Gaz. hebdom. de méd. et de chir.") has experimented with regard to its administration. The amount necessary to produce sleep varies from four to ten drops, which should be taken all at once, for divided doses do not succeed. The drug is scarcely soluble in water, and but slightly soluble in glycerin; but dissolves readily in alcohol. A syrup may be made in the following proportions:

Hypnone	1 drop;
Ninety per cent. alcohol	15 grains;
Syrup of orange-flowers	75 "
Syrup of cherry-laurel	15 "

Let the drop of hypnone fall into the alcohol, add the syrups, and keep in a tightly-stopped bottle. In like manner an elixir may be made of the following ingredients:

Hypnone	1 drop;
Sixty per cent. alcohol, Syrup of mint, each	45 grains.

The taste of these preparations is said to be very bearable. The drug itself has a very hot taste, and its odor reminds one of essence of bitter almonds, with a suggestion of wintergreen.

Iodol, a New Antiseptic.—The "St. Petersburger medicinische Wochenschrift" mentions iodol as a new antiseptic, and says that, while it is free from the unpleasant odor of iodoform, and does not produce poisoning when applied to wounds, it is not only a powerful antiseptic, but also a local anæsthetic, and favors the formation of granulations. It is prepared from ethereal animal oil (oleum animale æthereum), and is a fine crystalline powder, of a brownish color, almost insoluble in water, but readily soluble in alcohol, in ether, and in chloroform. It is precipitated from its alcoholic solution by the addition of water, but bears a considerable addition of glycerin without becoming turbid.

The Treatment of Lienteric Diarrhœa in Children.—M. J. Simon ("Progr. méd.") orders the following powders in cases of rebellious lienteric diarrhœa in children five or six years old:

Powdered crabs' eyes	15 grains;
Sodium bicarbonate	8 "
Magnesia	30 "
Calumba	4½ "
Nux vomica	1½ "

Divide into twenty powders, one to be taken twice a day, before eating. If the child refuses to take the powders, he orders:

Tincture of cinchona, " " rhubarb, " " calumba, each	75 grains;
" " nux vomica	8 "

Dose, five to ten drops, before each meal. In addition, the diet is to be regulated.

A Suppository for Chronic Cystitis.—The "Union médicale" publishes the following formula, attributed to Mallez:

Morphine hydrochlorate	⅙ to ⅓ grain;
Powdered stramonium	½ "
Cocoa butter	q. s.

For one suppository, to relieve the pain of chronic cystitis or that which follows lithotrity.

Original Communications.

VULVAR AND VAGINAL ENTEROCELE.*

BY T. GAILLARD THOMAS, M.D.,
SURGEON TO THE NEW YORK STATE WOMAN'S HOSPITAL.

THERE are five varieties of hernia which may show themselves in the vagina and vulva:

1. Cystocele, or hernia of the bladder.

2. Rectocele, or hernia of the anterior wall of the rectum.

3. Vaginal enterocele, or descent of a portion of the small intestines into the vagina.

4. Pudendal enterocele, pudendal hernia, or descent of the small intestines into the labium majus of one or both sides; and

5. Perineal enterocele, perineal hernia, or descent of the small intestines by protrusion through the perinæum.

Were one inclined to go very fully into detail, other varieties might be given, based upon the contents of these hernial sacs, in which the ovaries, the uterus, and the Fallopian tubes, either empty or filled with the products of conception, have in exceptional cases been found; or upon some extremely rare and extraordinary development of this condition—such, for example, as one case mentioned by Burns and quoted by Sir Astley Cooper,† in which the base of the bladder, passing down alongside of the right wall of the vagina, formed a hernia in the labium majus of that side. For practical purposes, the varieties of hernia which I have mentioned will, I think, fulfill all the requirements of the case.

As the title of this paper announces, I propose to pass by herniæ of the bladder and anterior wall of the rectum, merely with the mention of them which has been made, and to confine my remarks to descent of the intestines through the pelvic roof, and their protrusion into the labia majora, into the vagina, or through the perinæum.

Although these varieties of hernia have been known for at least a century and more, it is curious to see how very generally they have been ignored in systematic treatises upon gynæcology. And this is the more remarkable since errors in diagnosis of them are very liable to occur, and, when occurring, would put both practitioner and patient in a most deplorable position. To sustain this statement, let me refer to the most recent works upon gynæcology, which are now used as text-books by students of medicine in this country and in Europe. In the works of A. Martin, Hart and Barbour, and Emmet, no mention of vaginal and vulvar enterocele is made; in those of Barnes and Edis a mere mention is made, and in those of Courty and Thomas very short and unsatisfactory accounts are given.

Even in literature outside of systematic treatises, and in that of serial character, it is difficult to find much upon the subject. The truth of this will be appreciated from the statement that Littré and Robin, in their "Dictionnaire de médecine," published about ten years ago, quote largely, in their description of it, Sir Astley Cooper, who wrote as early as 1804.

In 1736, Garengeot was, according to A. Bérard,* the first to describe this form of hernia, and he was followed by Verdier, Hain, Sandifort, and Richter. As I have already stated, Sir Astley Cooper treated of it fully in his celebrated work upon hernia in 1804. The best account of it with which I have met is that given by A. Bérard in the "Dictionnaire de médecine," published in 1846.

Instances of this accident have been put on record by the following writers: Davis, in his "Principles and Practice of Obstetric Medicine," Levret, Gunz, Boivin and Dugès, Smellie, Fordyce Barker, and Peter Young, of Edinburgh. The last-named gentleman published a very interesting paper upon the subject in the "Edinburgh Medical Journal" for April, 1882, and put upon record a striking case which illustrates most of the important features of the lesion when occurring during parturition and soon after it. In the transactions of the New York Obstetrical Society for 1878 will be found a very able and exhaustive article upon the subject by Fordyce Barker, containing several illustrative cases occurring during pregnancy and parturition, and detailing a valuable case reported by Dr. B. A. Clements, U. S. Army, in which eight distinct attacks occurred.

VAGINAL ENTEROCELE.—This variety of the disorder consists in a descent of the intestines into the pelvic cavity, either in front of or posterior to the broad ligament of one side. As Boyer and Richter long ago pointed out, the intestines never descend directly in the median line, either anteriorly or posteriorly, on account of the intimate relations of the vagina at these points. They always descend a little obliquely, and most frequently posteriorly.

Usually the intestines alone descend in these hernial protrusions, but sometimes the omentum accompanies them; and Petrunti has reported one case in which the hernial tumor consisted of nothing but omentum. Usually, too, it is the small intestines which form the hernial protrusion, but Levret † has put one case on record in which the sigmoid flexure of the colon did so, and Boivin and Dugès ‡ mention one in which a portion of the large intestines came down as low as the perinæum and obstructed the vagina.

Vaginal hernia, as a rule, develops itself in the following manner, under the influence of causes which will soon be mentioned: A loop of intestine gradually pushes downward the prolongation of the peritonæum which forms the pouch of Douglas until it impinges upon the outside of the wall of the vagina and causes it to arch inward. This mechanical influence being continued and gradually increased, a tumor forms in the vaginal canal, inverts one wall of that canal more and more completely, and may end by escaping from the vulva and hanging outside the body, as a complete prolapse of the bladder or of the uterus would do.

* Read before the New York Academy of Medicine, December 17, 1885.

† "The Anatomy and Surgical Treatment of Abdominal Hernia," by Sir A. Cooper.

* "Dict. de médecine," tome xxx, p. 460.

† "Observations sur les polypes," Young's article, *loc. cit.*

‡ "Diseases of the Uterus," p. 511.

Under these circumstances it is evident that the tumor which protrudes has for its component parts—first, the inverted vaginal wall; second, the peritonæum; and, third, the intestines. Sir A. Cooper, in giving a description of these cases, says: "I wish it, however, to be understood that I have had no opportunity of examining this disease in the dead body, and that I am here describing it from what is known of the structure of the parts, and not from actual dissection." And Bérard, writing toward the year 1840 * and declaring that it is very important to know whether "the entire thickness of the vaginal wall is inverted and forms the envelope of the tumor, or if the external coat is torn so as to present an opening through which the hernia passes, carrying before it only the internal tunic of the vagina," asserts that at that time Sandifort was the only author who had reported an autopsy, and that he had neglected to mention this point. In looking up the literature of this subject, I find reports of several autopsies, and yet, so far as I have been able to ascertain, this point still remains unsettled.

Unquestionably the greatest danger which attends this form of hernia, and the same remark applies to the two other varieties which we shall consider, arises from the possibility of an error of diagnosis occurring from the practitioner's being off his guard, and therefore not sufficiently careful in the practice of differential diagnosis. The tumor occurring during labor and obstructing the progress of the fœtal head, a too rapid conclusion may be arrived at that an ovarian or parovarian cyst with a long pedicle has been pushed into the pelvis, a trocar and cannula are plunged in, and the operator is horrified at the escape of fæcal matter and intestinal gases. Or, if the condition be found to exist in the non-parturient woman, an effort is made to remove it, and, as this effort advances, the operator becomes painfully enlightened as to the error into which he has unfortunately fallen. Let me quote two cases to impress this important fact upon the minds of my hearers. The following is related in the "Centralblatt für Chirurgie," May, 1879: The woman, aged fifty-two, had had twelve children, the last born twelve years before. On examination, a swelling, about three inches long, reddish blue in color and covered by granulations and pus, protruded between the labia. A diagnosis of polypus of the uterus was made and the tumor removed. After suffering severe pain in the abdominal region for several hours, death ensued. Upon autopsy, there was found in the pelvis half a pound of liquid blood. A portion of the great omentum and a piece of the transverse colon had been cut away in the mass. In the posterior wall of the vagina there was an opening about five centimetres in diameter. Gunz relates the following: A woman had a tumor occupying one wall of the vagina and presenting at the vulva. A surgeon, mistaking it for an abscess, plunged a bistoury into it, intestines protruded, and the patient died of gangrene.

The most frequent cause for the varieties of hernia which we are considering to-night is parturition. Under the influence of utero-gestation all the pelvic tissues are greatly hypertrophied and relaxed, and, under the violent efforts of child-expulsion, the relaxed parts are strained by pressure from the intestines which are forced down upon them. Nevertheless, it must be borne in mind that some of the most striking cases of the accident which have been placed on record have occurred in nulliparous women. These are usually due to violent efforts, falls, and the previous existence of pelvic tumors which have burst or been removed.

Vaginal hernia, so long as it remains in the pelvic cavity and does not interfere with parturition, is usually a matter of little moment and the source of little inconvenience. As Klebs * points out, it is not prone to undergo strangulation, for the reason that, the peritoneal protrusion having no neck, constriction does not often occur. Under certain malign influences, however, occurring during parturition, as well as in the non-parturient state, such as pressure from the fœtal head, inflammatory processes, fæcal impaction, torsion of the contents of the sac, or the existence of a neoplasm, strangulation may occur.

The symptoms which are apt to develop are difficulty in locomotion, pelvic tenesmus, or "bearing down," colicky pains, dragging sensations, tendency to constipation, and, in time, vomiting. Should the accident complicate parturition, obstructed labor is apt to result.

Upon vaginal examination, a tumor of greater or less size is found in the vagina, and is diagnosticated by the following physical signs: It is supple, soft, and yielding; decreases upon pressure; gives a sense of gurgling to the finger if not to the ear; increases upon the patient's coughing or straining; yields resonance upon percussion, and is very generally reducible if the patient be placed in the knee-chest position and efficient taxis be practiced.

Vaginal enterocele may be confounded with the following conditions by a careless and rapid diagnostician: Prolapse of vagina, uterus, bladder, or rectum, or a combination of these displacements; with vaginal cyst, parovarian, or ovarian cyst; with a fibrous tumor presenting low down in the pelvis; with a "cold abscess" of the pelvis; or with a marked case of tubal dropsy.

It will be seen, by a review of the rational and physical signs already given, that the behavior of a true enterocele of the vagina under pressure differs very much from that which would characterize the pathological conditions just mentioned.

Why, then, it may be asked, is such caution inculcated with reference to the possibility of erroneous diagnosis?

Because error creeps in from the practitioner's being too confident, too much off his guard, and too little inclined to consider the possibility of a mistake. If he approach these cases calmly, philosophically, and in a proper spirit of diagnostic investigation, it is very improbable that an erroneous diagnosis will occur. Most cases present striking features.

Sir Astley Cooper's † description of a case seen by him is so graphic that I can not refrain from quoting it at length. The patient was "a young woman, aged twenty years, who had never had children, and whose case, I was informed by Mr. Stocker, apothecary of Guy's Hospital, was worth examination on account of a tumor projecting

* The second edition of the "Dict. de méd." appeared in 1846.

* "Path. Anat.," p. 970.

† *Op. cit.*

into the vagina. She was ordered to place herself in the recumbent posture with the shoulders a little elevated, and, an examination being made *per vaginam*, I felt a swelling a little above the os externum vaginæ, the size of which was that of a small billiard-ball. It was situated at the posterior part of the vagina, but rather to the left side; it was elastic and not at all painful to the touch. When I compressed it, it readily passed away, but, upon directing her to cough, it was reproduced. When I ordered her to place herself on her knees the swelling became very tense, and much larger than before, and, when she coughed, it dilated as any other hernia, but more forcibly.

"Having placed her again in the recumbent posture, I pressed the swelling entirely away by keeping the fingers about half a minute on the posterior part of the vagina, and then carrying the fingers higher up in the vagina, above the seat of the tumor, near to the os uteri, and, having pushed the vagina toward the rectum, I directed her to cough, and the tumor was not reproduced. Still pressing at the same part, I desired her to rise, and, so long as the pressure was sustained, the hernia did not return, but almost immediately, as the fingers were removed, the hernia became as large as before."

No description could be more graphic than this as applied to hernia occurring posterior to the broad ligament.

It must be borne in mind that, like hernia occurring elsewhere, those forms which we are now considering may show themselves in two ways: first, by a brusque and sudden development marked by alarming and decided symptoms; and, secondly, by a development so gradual and uneventful as to symptoms as to escape recognition entirely until the mere mechanical results of the hernial tumor force themselves upon the attention of patient or physician. At the end of this paper I shall relate a very striking and remarkable instance of the latter form of development. An equally striking illustration of the former is given by Dr. Young, in the article already referred to, in which all the symptoms of incarceration of the intestines rapidly and unmistakably showed themselves to be entirely relieved by successful taxis.

In certain very rare cases acute vaginal hernia occurs as a consequence of some traumatic influence destroying the continuity of this canal in its upper part. A striking instance of this, which occurred in the service of M. Auger, is reported by M. Pennel, in "La France médicale" for November, 1881. The patient, three months pregnant, endeavored to bring on abortion by the use of vaginal injections. One of these was immediately followed by violent colic, and in a few days after by abundant hæmorrhage which continued for several days. At that time a loop of intestines escaped from the vulva, which could readily be returned to the abdomen, but would at once prolapse. On the day after this occurrence the cæcum made its appearance, as evidenced by the presence of the vermiform appendix. In time this proved to be irreducible, and gangrene occurred, followed by escape of fæcal matter. During the progress of this condition abortion took place and a fœtus was expelled. In time the vaginal opening of the intestine closed entirely, fæcal matters passed normally, and the patient made not only a complete, but a rapid recovery.

Some years ago I called a consultation of two physicians in a case of interstitial pregnancy to decide the question of laparotomy. One of these gentlemen, anxious for an extremely thorough and conscientious diagnosis, refused to express an opinion until he had had the privilege of passing his entire hand into the vagina. I acceded to his wish, anæsthetized the patient, and his desire was fulfilled. As he withdrew his hand, however, a loop of intestine escaped from the vulva through a laceration which he had made in the upper part of the vaginal canal. I at once put the patient in Sims's position, introduced a speculum, and sewed up the rent. The patient recovered after having narrowly escaped death from acute peritonitis, and my colleague the annoyance of a suit for malpractice.

I once saw a similar hernia follow an attempt to replace a retroflexed uterus by a sponge probang in the hands of a most able and cautious gynæcologist. As the retroflexed fundus was pressed upon, the sponge suddenly burst through the vagina into the peritoneal cavity, and, being withdrawn, came forth entangled in a loop of small intestine. The examiner at once sewed up the opening with silver wire, and the patient recovered without a bad symptom.

It is not so much in the acute as in the gradually developing, creeping, insidious cases that the danger of erroneous diagnosis lies in ambush for the unwary and impulsive surgeon.

Pudendal Enterocele, or Pudendal Hernia, demonstrates its existence by the presence of an elastic tumor, about as large as a small hen's egg, or a pigeon's egg, about the middle of the labium majus of one side.

It may originate in two ways. As Paul Broca * has fully pointed out, the round ligaments of the female, which are the analogues of the spermatic cord of the male, after passing down through the inguinal canals, lose themselves in two glove-finger prolongations of fibrous character, which run down through the labia majora. Following the course of these ligaments through the abdominal rings and the inguinal canal the intestines sometimes descend, as they do along the spermatic cord in getting to the scrotum, and reach their ultimate point of descent in these dartoid sacs. Again, they sometimes reach the pudendum by passing downward between the vagina and the ramus of the ischium, thus reaching the labium majus from within the pelvis. In its commencement the latter variety resembles exactly vaginal hernia; but, instead of inverting the vagina before it as that does, it separates the vaginal wall from the ischium and insinuates itself between these parts.

Some of the French writers † divide hernia of the labia majora, or pudendal enterocele, into two varieties: first, "anterior labial hernia," or that which eventuates from the inguinal form; and, second, "posterior labial hernia, or labio-vaginal hernia," or hernia forming by extension of the peritonæum down in front of the broad ligament and alongside the vagina to the vulva.

* Cruveilhier's "Anatomy," chapter "External Organs of Generation."

† De Sinéty, "Manuel pratique de gynécologie."

From inguinal hernia ending by descent into the labium majus the internal variety may be thus distinguished: (1) the finger, pushing the tumor upward, will pass into the pelvic cavity between the ischium and vagina; (2) at the level of the os uteri, or thereabout, it will enter the pelvic roof; and, (3) pressure being maintained on the inguinal canal, and the patient being ordered to cough, it will, in spite of the pressure, recur.

In diagnosis the following conditions of the labia majora may be confounded with pudendal hernia:

Cyst or abscess of the vulvo-vaginal gland;

Cyst of the labium minus, or majus;

Abscess of the labium majus;

Fatty or fibrous tumor of the labium;

Tumors descending from the pelvic cavity.

Dr. Galabin reports, in the "Transactions of the Obstetrical Society of London" for 1884, what he believed to be a hydrocele, an egg-shaped cyst, two inches and a half long, translucent, occupying the labium majus. It had existed three years in a patient aged fourteen, been tapped once, and a straw-colored fluid removed. Dr. Galabin divided the skin on a director, and found a cyst free except at the anterior end toward the inguinal ring, where a firm cord was divided. The patient recovered.

Saenger (in "Arch. für Gynäkol.," vol. xvi) reports two cases in which the contents of labial herniæ were found to be tumors of the broad ligaments. In one case, reported by Hecker, the woman, aged forty, had noticed since childhood a tumor situated in the right labium majus. This mass, formerly easily returned into the abdomen, was at the time of operation irreducible. An incision was made over the tumor, which was found to be a myoma of the ligamentum rotundum; weight, three hundred and thirty grammes.

Paletta reports a case which was similar, a fibro-myoma of the round ligament being found as the contents of a labial hernia.

The differentiation of pudendal hernia from these conditions of the labia should be very carefully considered, for, if an erroneous diagnosis be made here, a fatal result might very probably prove the consequence.

The diagnostic signs which prove most reliable, and which may almost be styled pathognomonic, are these: First, airy feeling upon palpation; second, gurgling upon replacement; third, diminished tension in the dorsal decubitus; fourth, diminution of bulk upon taxis; fifth, resonance upon percussion; sixth, succussion upon coughing; and, seventh, intestinal pains of a colicky character.

As I have already said in reference to vaginal enterocele, there are no very great difficulties attending the differentiation of the disease. The danger is that the possibility of hernia at this point may be forgotten, and deductions drawn without considering it. Although the probability of error be not great, the appalling nature of the accident in which it would result warrants the relation of the following case, which is illustrative of its possibility: A patient called upon me with the following history: She had had an abscess just below the external abdominal ring, which, after poulticing, had been evacuated by her physician about a month before the time of her visit to me. After this she had felt well until a week before, when, after a muscular effort, the pain had returned with all the original signs of abscess, and these had continued, although she had painted the part steadily with tincture of iodine, as she had been directed to do in case of such an occurrence. Being in great haste at the moment, I examined the enlargement while the patient was standing, and, under a recent cicatrix which was painted with iodine, I discovered what I supposed to be a reaccumulation of pus. As the patient came to me, in the absence of her physician, merely for the evacuation of this, I placed her in the recumbent posture, and, lancet in hand, proceeded to operate. But, to my surprise, I discovered that change of posture diminished the size of the enlargement. This excited my suspicions, and, upon further examination, I found that a recent hernia had occurred under the old cicatrix.

Perineal hernia may affect both male and female. In the latter it consists of the descent of the intestines between the vagina and rectum, the advance being made posterior to the broad ligament, and continuing until the perineal muscles are forced apart, and the gut, with its peritoneal envelope, is arrested by the skin. In these cases Sir Astley Cooper declares that the hernial sac "protrudes as far as the skin of the perinæum, but does not project it so as to form an external tumor; its existence in the male can be only ascertained during life by an examination by the rectum; but in the female it may be felt both by the rectum and by the vagina. The sac lies between these two canals."

All these varieties of hernia are usually readily amenable to taxis, and this I have invariably in my experience found greatly facilitated by the knee-chest, or genu-pectoral, position. In some rare cases strangulation occurs. Under these circumstances the same surgical practice is indicated as in inguinal or crural hernia—namely, cautious opening of the sac and section of the constricting band by passing up a probe-pointed bistoury.

Before closing this paper, I desire to put upon record a remarkable case of extreme vaginal hernia, which presents some features which I have never met with in such literature of the subject as has fallen under my observation:

Mrs. K., a multipara of small figure and spare habit, thirty-nine years of age, residing in Middletown, Conn., called upon me in my office, and gave me the following history: About six years ago she noticed that a lump presented itself at the vulva, and that she began to suffer from difficulty in locomotion, frequent micturition, painful defæcation, dragging in the back and loins, colicky pains in the bowels, and general nervousness and malaise. During the past six years this tumor had steadily increased in size, until it had come down to the middle of the thigh on the right side. At the time I saw her she was greatly emaciated, and suffered so much from the symptoms which have been enumerated that she felt that any resource which held out the prospect of even partial relief would be a boon to her. While the tumor hung out of the pelvis, she could neither stand, walk, nor sit with any comfort, and when by taxis it was restored to the pelvis, she found it so very difficult and painful to empty the bladder and rectum that she was compelled voluntarily to force it out again.

Upon physical examination, as the patient lay upon the back, I discovered a large pinkish-colored tumor hanging from the vulva, as represented in Fig. 1, and presenting all the gross

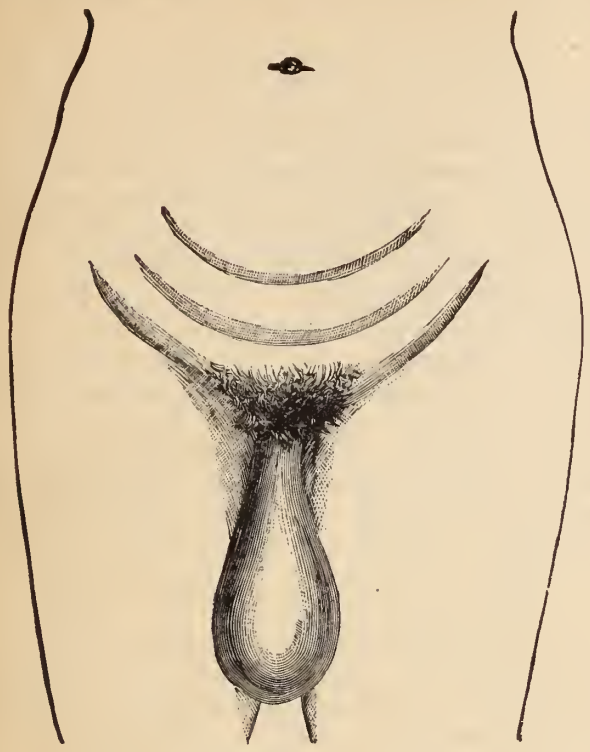

Fig. 1.

appearances of a huge cystocele. As soon as a minute examination was made it at once became evident that this superficial impression was entirely erroneous. The index-finger being passed around the tumor and up the vagina, the tumor was found to be attached to the ischium on the right side of the vulva, so that there was no vaginal space there at all, while on the left side it passed up readily and discovered the uterus almost out of reach in the left side of the pelvis. A catheter being passed into the bladder, that viscus was found high up above the pubes and obliquely in front of the uterus.

Taxis being practiced in the knee-chest position, the tumor disappeared with a very slight gurgle, its contents evidently retreating into the pelvis through an opening on the right side. Only once in manipulating the mass did a slight gurgling sound make itself manifest; resonance upon percussion did not appear distinctly, and yet there could be no doubt that hernia did exist. After the contents of the sac were returned to the abdomen it was evident that their retention there, or even the retention of the sac itself within the pelvis, would prove impossible by any mechanical contrivance which could be devised, for two reasons—first, the great weight of the mass; and, second, the fact that pressure of it against the bladder and rectum when it was returned to the body interfered so greatly with the functions of these viscera as to render the patient utterly uncomfortable.

And yet the deplorable condition of the patient and her great mental and bodily distress urgently called for active interference. She had consulted many medical men, had been discouraged from seeking surgical relief, while all lesser methods had failed to give her aid, and now both she and her husband were desperate, and willing to adopt any plan which held out the least hope for them.

It was under these circumstances that I suggested the following operation: I proposed to perform laparotomy; cause an assistant to keep the hernial sac well within the pelvis by one hand in the vagina; pull all the contents out of the sac; seize this at its most dependent portion (A, Fig. 2), drag it up into

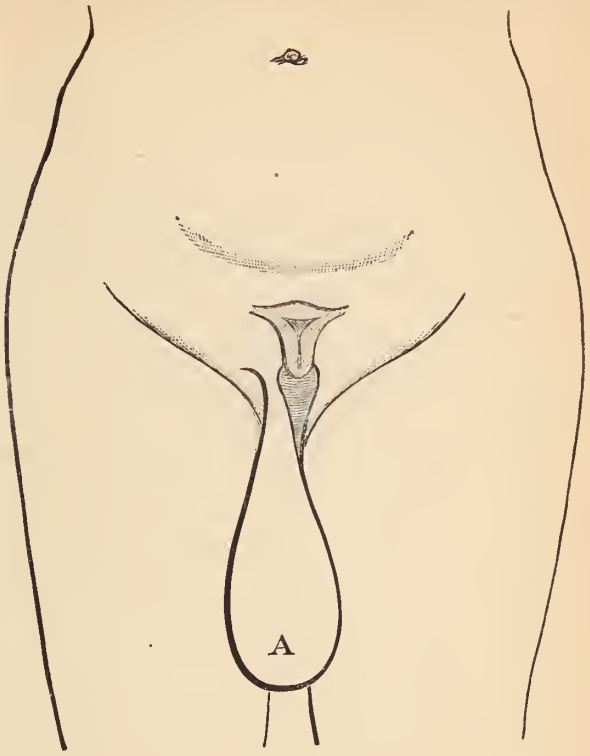

Fig. 2.

the abdominal wound (Fig. 3), and fasten it there by suture, sustaining the heavy sac, meanwhile, by two knitting-needles passed through and lying flat across the abdomen (Fig. 4).

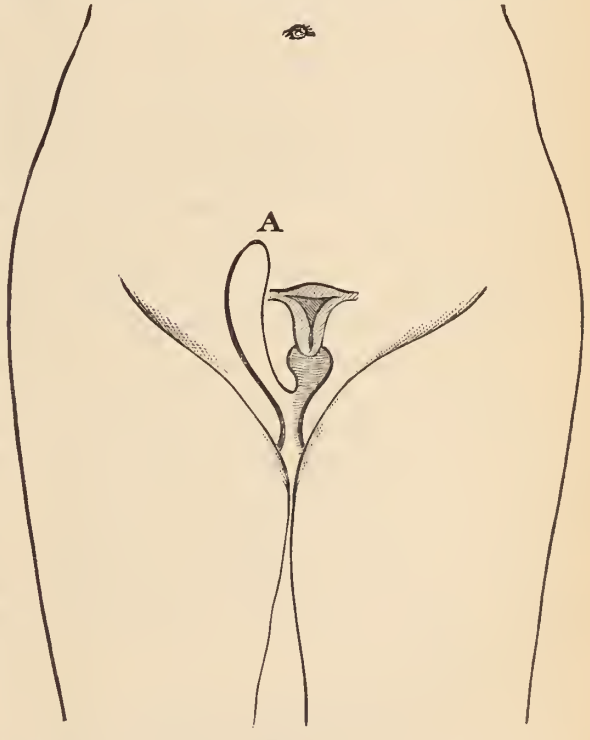

Fig. 3.

As soon as this was explained to them they eagerly accepted the proposal, and the patient entered my service in the Woman's Hospital. There Dr. Emmet and Dr. Bozeman saw her with me, agreed in the diagnosis, and indorsed the operation proposed.

Upon cutting through the abdominal wall, after an assistant had, as I have stated he was to do, pushed the hernial mass

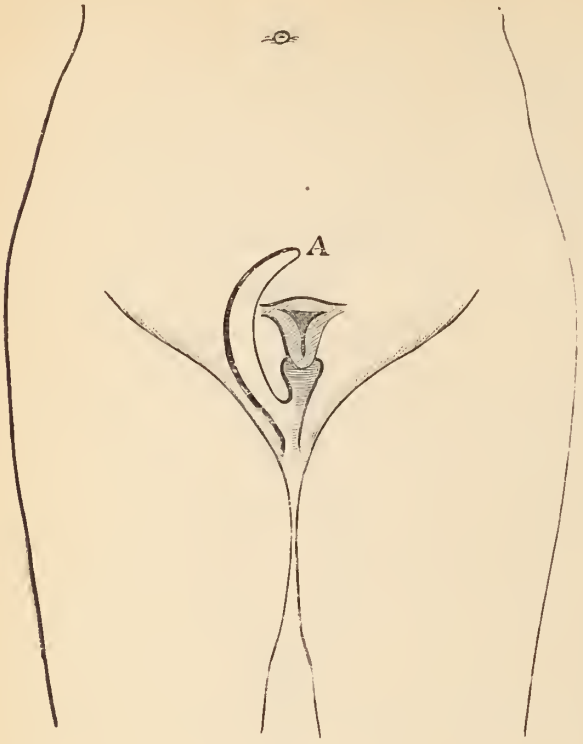

Fig. 4.

back into the pelvis, I was surprised to find in the pelvis a soft, fibrous tumor, which had evidently been pushed up from below, on a level with the symphysis pubis. It was very movable, covered by peritonæum, disconnected with the uterus, and, upon careful examination, proved to have no connection with the bladder. I was entirely at a loss to determine its relations, but, in view of the desperate character of the case, decided at once to remove it. This I did by splitting the peritoneal covering, tying a number of bleeding vessels, draining the sac with a glass tube, and fastening the sac into the abdominal wound, as I have said that I proposed to do. The patient made a good recovery, and so far, more than a month having now passed since the operation, has continued to be free from any return of the hernia. I confess that I feel apprehensive about the future, but the present is quite gratifying and completely satisfactory.

My explanation of the case is this: This very movable tumor, which appeared to have no fixed anchorage in the pelvis, had originally pushed the vagina before it by entering the pelvic cavity behind the broad ligament of the right side; the intestines had pressed down upon this, and together they had made up the contents of the sac.

And now the question suggests itself, What was the nature of this tumor? Dr. Coe, the pathologist of the Woman's Hospital, has furnished me the following report of his examination of it:

"*Report on Specimen removed by Dr. Thomas at the Woman's Hospital, November 12, 1885.*

"*Gross Appearance.*—A soft, shapeless mass of tissue, which bears a certain resemblance to an hypertrophied bladder.

"Weight, 10 ounces.

"Measurements, 22 × 15 ctm.

"Average thickness, 1·5–2 ctm.

"The growth is covered in some places by a layer of peritonæum, and over its exterior are numerous torn pieces of tissue, marking the sites of adhesions. The vascular supply of the exterior of the mass is quite extensive, but its interior is bloodless and poor in vessels.

"On section, no signs of cyst-formation can be found; nothing but a softened, œdematous, fibrous tissue. This tissue is easily separated by the fingers so as to form pseudo-cavities, but no true, preformed cavity is present anywhere.

"The tissue varies in color at different points. On holding the mass up to the light, it is seen to be traversed by bundles, or trabeculæ, of reddish fibers (smooth muscle?), which offer a contrast to the general whitish ground of the tumor.

"*Microscopically*, (1) The growth consists of ordinary fibro-muscular tissue, similar to that of a uterine myo-fibroma. Vessels are few in number.

"(2) The fluid squeezed from the interstices of the tissue is colorless, and contains no cellular elements, except a few blood-corpuscles (lymph?).

"(3) The tissue, covering the exterior of the growth, is a delicate membrane, strengthened by interlacing fibers of connective tissue, in the meshes of which are numerous large, epithelioid cells. Nerve-fibers and blood-vessels cross the field in all directions.

"*Inferences.*—(1) This is not an organ, *i. e.*, the bladder.

"(2) It is not an ovarian cyst.

"(3) It is not composed (at least to any great extent) of inflammatory tissue.

"What is it? I submit two theories, both of which are merely theories—viz.:

"(1) The growth is a local hypertrophy of the pelvic connective tissue.

"(2) It is a sub-peritoneal uterine fibroid, which has become thoroughly œdematous.

"I incline to the former view for the following reasons:

"1. The situation of the mass at the time of operation, as described to me.

"2. The absence of a distinct pedicle.

"3. The absence of a complete peritoneal covering.

"4. The absence of any 'géodes,' or cavities, in the mass, such as are almost invariably found in a softened fibroid.

"Finally, the *tout ensemble* of the tumor, which forbids the thought that it has ever been a firm, hard growth, such as a fibroid.

"*Origin of the Growth.*—The presence of adhesions, in which the mass was buried, the dilated condition of the blood-vessels in those adhesions, and the general œdema of the tissue, all point to some obstruction of the circulation in the tumor. It is not difficult to regard this phenomenal appearance as due to simply a localized œdema of the pelvic connective tissue."

(Signed) H. C. Coe.

That this tumor had no connection whatever with the uterus or bladder I feel quite sure. My impression is that it belongs, as Dr. Coe's report intimates, to a somewhat rare class of tumor, arising from the pelvic areolar tissue or the round ligaments, of which quite a number have been recently reported by German pathologists.

Dr. McCosh has kindly looked up the subject for me, and I present some of his researches.

A. Martin, in his recent work upon the "Diseases of Women," says: "In the broad ligaments are to be found, also, solid tumors which are described as myoma or fibro-myoma. They are not connected with the uterus, but spread out between the epithelial layers of the ligamentum latum,

and can from that point develop as large abdominal tumors, or may grow downward toward the vagina, and, finally, at the side of the vagina, bulge out as far as the vulva, where they present themselves for operation. In rare cases they have pushed through the great ischiadic foramen."

The same author also reports the case of a woman who complained of great weight and vaginal pressure. On examination, he found a prolapsus of the anterior vaginal wall, and also of the posterior, Douglas's pouch being filled with a soft mass which seemed to arise on one side of the uterus. He performed laparotomy, and found the mass to consist of an œdematous fibro-myoma of the broad ligament.

Schmidt reports a case of a solid tumor attached by a pedicle to the broad ligament, which caused marked prolapse of the anterior vaginal wall.

Schröder acknowledges the existence "of connective-tissue tumors, of very soft consistence, which are saturated with fluid, and which arise in the pelvic connective tissue, and in this situation (subserous) continue to develop.

"Their anatomical relations correspond to subserous ovarian cysts," etc.

M. Hofmeier ("Gesellsch. f. Geb. und Gyn.," Berlin, October 24, 1885) reports a tumor, of the size of the fist, situated between the anterior vaginal wall and the urethra, causing a decided prolapse, and projecting above the level of the vaginal wall to the size of an egg, the spot being somewhat ulcerated. After division of the capsule, it was easily enucleated. Its attachment was deep in the connective tissue of the pelvis; and it belonged to the rare class of soft fibroid tumors of pelvic connective tissue.

It is highly probable that the tumor which I removed belonged to one of these curious and rare classes.

Unfortunately, little can be said concerning the treatment of vaginal and vulvar herniæ, for the reason that there is but one variety, the pudendal, which eventuates from inguinal hernia, for which very much can be done. That variety is as amenable to treatment by the ordinary truss as inguinal hernia is. The other varieties can, to a limited degree, be relieved by pessaries, perineal pads, abdominal bandages, etc.; but we are poor in methods of decided relief, and utterly wanting in those of cure. It appears to me that the plan suggested, and partially carried out in the case which I have related, promises more than any other which has yet been brought forward; but of the validity of this surmise time and experience must give the proof. Certain I am that, if another case of large vaginal hernia presented itself, I should feel inclined to try laparotomy, dragging up the sac and fastening it in the abdominal wound.

B. Schmid says ("Handbuch f. Chir.," Billroth und Pitha) that attempts were made by Huguier at radical cure of vaginal hernia by an oval excision of part of the posterior vaginal wall and closure by suture, but without any lasting result. He must, indeed, be a sanguine surgeon who hopes for much from such procedures.

Errata.—In the report of Dr. R. J. Hall's remarks on the bacillus of syphilis, published in our issue of December 12th, page 671, for "Süssgarten," *passim*, read *Lustgarten;* and, for "giaconic," read *de Giacomi.*

ADHESION OF THE SOFT PALATE TO THE WALL OF THE PHARYNX.*

By CLARENCE C. RICE, M. D.

In reviewing the literature relating to this class of cases, one must conclude that very little has been accomplished for their relief. It would appear that, where this unfortunate condition has existed, as a rule no surgical measures have been attempted. In the records where the line of treatment has been indicated, nothing more than temporary benefit seems either to have been sought or obtained. In the histories of a considerable number of these cases, where there was almost complete occlusion of the middle pharynx, we find the lesion accurately described, but no allusion made to operative procedure. Many of the systematic treatises on surgery refer to partial destruction of the pharynx by ulcerative process, but no mention is made of resulting adhesion of the mucous surfaces. The difficulty of reaching the affected part, dangerous hæmorrhage from an inaccessible quarter, and the strong tendency to recurrence after the adhesions were separated—these were sufficient obstacles to deter the surgeon, and to make the prognosis of successful operation doubtful. Fifty or even thirty years ago—before the days of the rhinoscopic mirror, when little could be seen, the operator working in the dark and mapping out landmarks with his finger—it does not seem strange that surgeons avoided post-nasal operations whenever the demand for interference was not imperative.

Writers of to-day present a prognosis hardly less gloomy. Verneuil remarks that "nothing is easier than to separate adhesions, and nothing more difficult than to prevent their recurrence." Mackenzie says that "great relief can be afforded to the patient as long as he remains under treatment; but no cure can be predicted, as the stenosis always returns when mechanical measures are suspended." Sémon's opinion is, "that attempts at dilatation are only of service so long as used." Cohen says that "the tendency to reunion is very great; that he has seen a number of these operations performed with very little benefit." And Bosworth: "It must be confessed that at present we possess no means of remedying this frequently distressing condition; all that lies in our power is simply to palliate some of the most prominent symptoms." In view of such opinion, the operator will hardly welcome this class of patients to his office. But such prognosis, I think, may be misleading. The same verdict should not be applied to all cases, since the lesions caused by inflammatory ulceration in the upper and middle pharynx differ so greatly as to location and extent. It is not to be expected that a pharynx in which all semblance of mucous membrane has disappeared, and the muscular tissue been replaced by a fibrous structure, can ever give its owner much happiness. Comfort may be left out of the reckoning; but that such a pharynx may be made available for the passage of air, that the nasal voice may be corrected, and the sense of smell partially restored, is quite possible.

* Read before the American Laryngological Association, June 25, 1885.

In considering the prognosis, these cases should be divided into two classes:

1st. Where the *sole lesion is the adhesion of the soft palate to the walls of the pharynx*, and

2d. *Where, in addition to this, extensive cicatrization has narrowed the normal caliber of the naso-pharynx.* In determining the probable success of surgical treatment it is most important to ascertain to which of these classes the patient belongs. Has the ulcerative process extended above the level of the soft palate? and have the deeper tissues been involved? These are the questions to be decided. My own experience would lead me to believe that in the majority of instances the deformities are occasioned by superficial rather than deep ulceration. Union of the soft palate and pharyngeal wall may be a result of simple erosions, and that, too, when only one surface is involved. Here the cicatricial stricture is, of course, less formidable and more amenable to treatment than where there is deeper destruction.

Belonging to the second class is a case reported by Dr. William Turner,* and referred to in Dr. Cohen's book. It was one of almost complete occlusion between the middle and superior pharynx. An autopsy showed that very extensive changes had taken place. The anterior pillars were normal, but the uvula had disappeared, and the posterior pillars had become absorbed in the union of surfaces. On removal of the pharynx from the vertebral column, the deep muscular structures were found to be almost wholly altered. Subsequent contraction had greatly diminished the diameters of the pharynx. Although about normal at its superior extremity, it gradually became narrower below, until at the level of the hamular process the lateral diameter was not more than half an inch. This point corresponded in location with the junction of palate and pharynx. Below, the tube became enlarged. Dissection demonstrated that the muscular fibers of the superior and the upper portion of the middle constrictor muscles were entirely replaced by connective tissue. The palatal muscles were not changed.

This autopsy teaches the importance of an early diagnosis, that the ulcerations may be controlled before they involve the deep structures and produce lasting deformity. To my mind, the contraction of the pharynx above the line of adhesion is the most discouraging feature in the treatment of these cases. I believe it is much easier to separate adhesions and to prevent their recurrence than to enlarge the cicatrized pharynx. In searching for the cause of nasal dyspnœa and pharyngeal discomfort, too much stress has been placed on the adhesions, which are to be plainly seen in the back of the mouth, and too little on the narrowed tube above, which can not be so readily observed. It is for this reason that the operator is frequently disappointed in the small improvement in nasal breathing after he has freed the adherent surfaces. The trouble above remains.

The highest grade of contraction occurs in hospital and dispensary practice, where we find those unfortunates who, in addition to an hereditary scrofulous or tuberculous diathesis, have acquired the syphilitic poison. Ulcerations under such conditions are rapid and destructive, and frequently have attacked all the soft parts before the patient comes under medical supervision. Extensive disorganization often takes place behind the soft palate or pharyngeal pillars before physician or patient is aware of anything more serious than an ordinary sore throat, pain not being always a prominent symptom. The physician should be suspicious of any painful affection of the pharynx the cause of which is not apparent and which does not yield readily to treatment; such a case should have the benefit of a rhinoscopical examination at once.

Ulcerations of the pharynx have gained the reputation of being insidious, because they often attack primarily parts which are not easily seen. The angle of the pharynx behind the posterior pillars is a favorable location for the commencement of ulceration, which in this hidden pocket is apt to escape observation. I have seen a number of cases where this was the first point of attack. I remember an interesting example of this kind where the progress of inflammation was easily studied on account of a wide cleft in the palate. The child was suffering from scrofula or congenital syphilis. The mucous membrane showed a constant tendency to degenerate, and the posterior surfaces of the pillars were always the first localities to succumb. Constant friction between the mucous surfaces at this point and the retention of irritating secretion are exciting causes. Superficial ulcerations undoubtedly occur here during attacks of simple pharyngitis which are repaired without adhesion. It is in those cases where the syphilitic or tuberculous dyscrasia are present that we find the evidence of a destructive process.

Erosions or superficial ulcerations may escape detection even when located in plain view. There may be so little change in color, and the depth of the ulceration may be so slight, that loss of tissue is determined more by the fact that the surface bleeds when touched than by its gross appearances.

In addition to adhesion and cicatrization, another pathological change takes place which renders these cases difficult to treat satisfactorily, and this is the formation of new connective tissue. Not only is the normal structure replaced by it, but there is actual hypertrophy, which diminishes the diameters of the pharynx in all directions. This condition compromises the success of operative measures.

The process of inflammation and cicatrization is an interesting one. The soft palate, almost wholly a muscular structure, is so constantly in motion that it would seem impossible for it to become adherent to neighboring structures; but this result follows quite easily and naturally. The pillars of the pharynx, as has been said, are first involved, and later the soft palate is drawn to the posterior wall of the pharynx. This is accomplished in two stages: the first is the retraction of the palatal muscles, which have become shortened by the loss of tissue, consequent upon ulceration, and the second is the union of the pillars to the wall of the pharynx. The palate is thus forcibly drawn backward, little by little, until it rests upon the back of the

* "Edinb. Med. Journal," January, 1860, p. 612.

mouth. The ulceration extends to it from the sides, and the mischief is done. The unsymmetrical appearance of the palate indicates where the disease began and the course it followed, for all the tissues are drawn toward the point first attacked. The tendency to adhesion is increased whenever the muscular tone and mobility of the palate are diminished. This is true also in perforations of the palate, since the current of air passes through the artificial opening and no longer diverts the uvula from the back of the mouth.

The occlusion between the middle and upper pharynx is frequently nearly complete, only a small communication remaining. Dr. Bosworth says: "A perfect closure never occurs"; and my observation tallies with his. But Dr. William Turner, at the time of writing the article already referred to, stated that he had just had a case reported to him by Dr. W. H. Flower, assistant surgeon of the Middlesex Hospital, where there was complete occlusion.

The ætiology of pharyngeal ulcerations is well known. They rarely occur in the simple varieties of pharyngitis, but are a frequent complication of the eruptive fevers and typhoid, diphtheria, scrofula, syphilis, tuberculosis, lupus, phagedæna, epithelioma, etc., and sometimes result from post-pharyngeal abscess, caries of the vertebræ, and traumatism.

It is unnecessary to enlarge upon this, but it is wise to appreciate these well-known pathological changes, because the prognosis will depend wholly upon their nature and extent.

It is not an uncommon occurrence to find patients, in the throat-wards of hospitals, suffering with pharyngeal adhesions. Usually they obtain little relief and remain as long as they are permitted. I am unable to speak definitely of several cases which I saw in the hospital, as they did not specially interest me at the time. In private practice they are much less frequently seen.

The first case I had the opportunity of studying was at the office of the first president of this society, the memory of whose good works we honor and whose loss we to-day lament. I am confident that the cheerfulness and assurance with which he operated, and the good results he obtained, grounded me in the belief that much could be done for the relief of these unfortunate ones. In the case referred to, Dr. Elsberg used the blunt-pointed staphylorrhaphy knife in separating the soft palate from the pharynx. He made forcible dilatation with his finger, and, to prevent reunion, gave the patient a hard-rubber palate-retractor, and instructed him to draw the palate forward many times each day. This procedure was successful in largely benefiting the patient.

The operations performed to separate adhesions have differed but little. Before the day of the galvano-cautery most surgeons seem to have preferred gradual dilatation by means of bougies, sounds, sponge-tents, air-bags, etc., and rapid dilatation with the finger, to the use of the knife. The danger of hæmorrhage was deemed a strong argument in favor of non-cutting instruments. It was the general opinion, too, that, if cut surfaces were made, they would again become adherent, with an increased amount of contraction. Rothenberg made an advance step when he recommended that a portion of the cicatricial tissue be excised, and so, after separating the surfaces, he dissected off the rough edges with forceps and scalpel.

Diefenbach passed ligatures through the soft palate, drew it forward as far as possible, and held it away from the pharyngeal wall by fastening the cords around the ears.

Dr. A. P. Cook, of Kentucky, describes, in the Philadelphia "Medical and Surgical Reporter" of March, 1873, an interesting and, at that time, an original plan for keeping the ulcerative surfaces apart. The case was one of syphilitic ulceration. The entire palate was adherent, with the exception of a minute opening, through which only a small probe could be passed. He used specially devised knives, the blades at right angles to the shaft. With the handle of a tablespoon, introduced behind the palate, he measured the extent of separated surfaces; he then hammered out a piece of sheet lead to the required size, and suspended it behind the veil of the palate by two strings which were passed through the nostrils. The patient wore this constantly for six weeks. The writer says: "It did not interfere with deglutition, and successfully prevented readhesion." If such an interposing medium can be worn without too much discomfort, it is certainly more efficacious than pieces of lint, and is more comfortable than forcible traction by means of ligatures.

At times it has been deemed advisable to guard against hæmorrhage by preliminary tracheotomy. Dr. T. Gilbert Smith, of London, arrived at the following conclusions: (1) Tracheotomy; (2) divisions of adhesions with guarded knife; (3) a number of notches are preferable to a long incision; (4) cutting should be done from above downward, that the whole wounded surface may be seen. These instructions are more pertinent to strictures of the lower pharynx. J. William White, in Holmes's "Surgery," recommends that an artificial opening be made through the soft palate in cases where there would be great difficulty in preventing readhesion. The main object, he says, in such operation is to restore the sense of smell. It is also suggested that, after severing attachments, longitudinal incisions through the palate be made, to counteract muscular contraction and to prevent the palate, as a whole, from being brought against the pharynx. But the condition established by operations of this kind is hardly preferable to a closed naso-pharynx.

An article by von Lesser,* of Leipsic, having the attractive title "A New Procedure for the Separation of the Soft Palate from the Wall of the Pharynx," describes the following operation:

"Patient was syphilitic; surfaces were adherent, except at small opening near uvula. This free portion was split parallel to its surface; the anterior plate was divided into halves by a median longitudinal section; the lateral halves were detached from pharyngeal wall; the freshened surface of the triangular apex of posterior plate was united with the wounded angle of the anterior plate. Finally, each detached half of the anterior plate was duplicated, the medial edge of the wound being turned backward and outward, and

* "Berlin. klin. Wochensch.," No. 23, 1879.

fixed by sutures in this position. The mucous membrane of the lateral portions of velum thus faced the wounded surface of the pharynx. Reunion was in this way prevented."

In closing, I will briefly report the history of a patient I saw at my office. The plan of treatment followed presents but few original points. In fact, there seems to be little opportunity for new surgical methods here, but I believe that persevering work will do much for these patients, and they will not be condemned as incurables:

Case.—Mrs. J., aged thirty-eight, married in her twenty-second year, mother of five children, consulted me in March, 1883. Her husband was a prosperous business man. She occupied a good social position at her home in a Southern city. She was of healthy parentage, though there had been several deaths from phthisis in her father's family. Patient was of average height, pale, somewhat emaciated, and I was impressed with her careworn expression. She breathed noisily through the mouth; sense of smell gone; voice nasal. She complained of a feeling of great dryness and discomfort at the back of the nose and mouth. She was unable to clear the pharynx of tenacious mucus, which always collected there, and which constantly annoyed her. She swallowed with some difficulty, and liquids frequently passed into her nose. She was extremely nervous, a condition exaggerated by tinnitus of the left ear. Hearing was impaired on both sides. She had a hacking cough, and had lost fifteen pounds in weight.

She gave this history of her malady: Her health was good until the birth of her last child, three years previous. Confinement was followed by pelvic cellulitis. She recovered after serious illness, lasting several months. It was while convalescing that she was attacked with sore throat. She remembered only that swallowing was painful, but there was not much discomfort when her throat was at rest. These symptoms lasted two weeks, and interfered but little with her recovery. Her physician prescribed gargles, and she supposed that her throat was entirely well. It was some weeks later, when she found it difficult to breathe through the nose and there was a feeling of constriction in the back of the mouth, that she suspected something was wrong. She says that neither the physician nor herself was aware of any ulceration, and this is to be credited because there were no cicatrices below the junction of the mucous surfaces. The physician who attended her died two years later, so that I was wholly dependent upon the patient for these facts. In regard to causation, the most careful inquiries of the patient and her husband produced no evidence that it was a syphilitic lesion. I could find absolutely nothing to base such an opinion upon. The character of the people was such that their statements were to be believed.

The type of the ulceration was probably either scrofulous or tuberculous, since the patient was suffering from bronchial catarrh, and there was consolidation at apex of left lung. Her respirations, about thirty per minute, seemed unduly increased, considering the amount of pulmonary trouble, but the frequency was due to the necessity of mouth-breathing and the discomfort of a dry pharynx. The back of the mouth presented a very unsymmetrical appearance; all the soft structures were drawn to the right. The right pillars were blended in one mass, and on the left the pillars, as well as the uvula, had been drawn half an inch out of position before they had become adherent to the wall of the pharynx. An opening, one fourth of an inch in diameter, at the right of the uvula, was the only communication with the posterior nares.

The patient was under treatment for two months. The plan adopted was as follows: I dilated the passage with steel sounds until it was large enough to admit the finger (which, after all, is the best dilator). Traction was then made until the opening measured three fourths of an inch across. A small curved sound was passed for the purpose of exploring the lateral attachments. On the right side the point of the sound could be carried downward behind the posterior pillars for a considerable distance. Using the sound as a guide, I burned through to it, with the galvano-cautery knife, at the junction of the mucous surfaces, establishing a second communication. A platinum wire was passed through the opening just made, and drawn out through the original aperture into the mouth. The loop was threaded through an insulated cannula attached to a cautery battery. The adhesions included within the wire were separated by shortening the loop and passing a current through it. The cannula was bent at right angles, point upward, so that the snare was tightened in a direction parallel with the posterior wall of the pharynx.

I repeated the same procedure in dissecting off the uvula, and twice more in detaching the left side of the velum. Here it was necessary to burn through more tissue, as the adhesions extended higher up. Division of the bands near the left Eustachian orifice relieved materially the tinnitus. There was no hæmorrhage. Traction was constantly made with the finger by the patient as well as myself. In addition, she used a hard-rubber palate-hook every few hours. For a time I had the patient wear at night a plate of hard rubber of proper size, one eighth of an inch thick, with rounded edges, suspended by cords through the nostrils. It gave little discomfort, and may have aided in keeping the surfaces apart, though I consider continued traction of the soft palate the most important means of preventing readhesion. There is far less danger of secondary union when the tissues are separated with the galvano cautery loop, as the edges are thus thoroughly cauterized. The patient was able to breathe through the nose comfortably, and the sense of smell was restored to a large extent.

I treated a case last winter very much like the one here reported.

A man, thirty-five years of age, in good health. The soft palate was adherent to the wall of the pharynx along the greater part of its border, the result of syphilitic ulceration. The tissues were separated in the same manner by the galvano-cautery loop, and reunion was prevented by the same method used in the former case. But here I had the benefit of the use of cocaine, which is of immense advantage, not only in the relief of pain, but in a much more important particular—the control of muscular action. By a free use of cocaine the soft palate can be made nearly immovable, so that, after being freed from the pharyngeal wall, it hangs directly downward, and does not continually invite reunion by being in contact with the neighboring mucous surfaces. A third advantage is that it diminishes the inflammatory reaction necessary to repair.

DISCUSSION.

Dr. Mackenzie: I question strongly the diagnosis of tubercular or scrofulous ulceration in the class of cases reported by Dr. Rice. The localization of tubercular ulceration in the naso-pharynx, especially when associated with cicatrices, if it exist, must be the rarest of pathological events. I regard the large majority of these cases as syphilitic, although the same result may be brought about through the ulceration which follows diphtheria, the essential fevers, and other forms of blood-poisoning. The social standing counts for nothing in the diagnosis.

I would like to say, in reply to Dr. Ingals, that, while it would be a great pity to call all destructive ulceration in the naso-

pharynx syphilitic, it would be a still greater pity, in uncertain cases, not to give the patient the benefit of the doubt. I should like to call special attention to the peculiar tendency of syphilitic lesions to isolation in some portion of the upper respiratory tract, and this long after the disease has apparently run its course; or, in another class of cases, where there has been no previous history of syphilis. In such cases a tertiary ulcer in the nose, on the palate or in the larynx, or even trachea, may be the first thing to call attention to the existence of syphilis.

This tendency of the syphilitic virus to crop out in some portion of the upper air-passages, without pre-existing syphilitic lesions in other parts of the body, or long after the original disease has apparently spent its force, is a point of considerable interest. In this connection, too, I may cite the case reported by me in the "Wiener medicinische Jahrbücher" in 1881, in which the trachea was the seat of isolated syphilitic lesions; and another reported last year in Baltimore, where, on autopsy, the only evidences of syphilis were unmistakable signs of that disease in the nasal passages.

Dr. Robertson: This high-arched condition of the palate and its frequent occurrence in syphilis have been explained as being due to the loss of permanent teeth. From this, contraction of the jaw results and arching follows. The same would occur in congenital syphilis from the frequency with which the teeth are lost.

Dr. De Blois: I think Dr. Mackenzie's remarks are too sweeping, for, in my limited experience, I have had three cases of ulceration under the velum and in the position to produce adhesions. I know these cases were tuberculous, for the patients died of tuberculosis, and post-mortem examinations were made. Adhesions had not taken place, but there is no reason why they should not have.

Dr. Delavan: The subject of Dr. Rice's interesting paper was presented to this association several years ago in an elaborate article by Dr. A. H. Smith. In this Dr. Smith referred to a case of syphilitic adhesion which I reported to him, in which I had operated successfully by separating the attachments of the velum with the pharynx and immediately applying to the incised surfaces pure mono-chloracetic acid. Healing took place without adhesion, and the result was remarkably good.

Dr. Ingals: I believe that most of the cases are syphilitic, as has been claimed, but it is too bad to call all patients syphilitic in whom we do not know what is the matter. I have recently seen a case in which the mode of operation was easy and satisfactory, at least for the time being. The patient had adhesions both of the palate and tongue to the pharynx. The opening below was so small as to greatly interfere with swallowing and breathing, being not more than three eighths of an inch in length by an eighth of an inch in breadth. He attempted to divide the adhesions, which were very extensive, by cutting through them with the galvano-cautery knife; but the proceeding was very slow, and, after a couple of applications, the patient was allowed to sit aside while other patients were being seen. He soon sent word that he was choking. I then found that there had already been swelling as the result of the canterization, which was so great as to make it unsafe either to leave the patient in his present condition or to repeat the operation. I then incised the adhesions with a knife bent at a right angle, cutting about an inch on one side and nearly as far on the other, with the result of making an opening through which the largest œsophageal bougie (more than half an inch in diameter) could be passed. The adhesions above had been easily divided by means of bent scissors such as are used by gynæcologists. The patient left the city for his home within a couple of weeks, so that the ultimate result was unknown.

Dr. Rice: I am always pleased to be able to satisfy myself of the absence of syphilis in a case, because I believe that many physicians are overfond of finding this disease, and that it is already burdened with lesions frequently due to some other malady. It is the duty of every physician to place the blame where it belongs. The majority of the cases of adhesive inflammation are syphilitic. My first case, so far as could be ascertained, was not. A pelvic cellulitis, following a severe confinement, was the exciting cause. The predisposing causes were a moderately bad family history, a severe grade of catarrhal inflammation of the upper air-passages, and the first stage of phthisis of one lung. I believe such a combination of pathological conditions sufficient to occasionally cause a post-nasal or pharyngeal catarrh to assume an ulcerative and adhesive form—the so-called scrofulous inflammation. The use of the galvano-cautery knife, as described by Dr. Ingals, is very tedious, so little tissue can be separated at one time, and readhesion rapidly takes place. The use of the platinum loop, as described in this paper, is very satisfactory. There is but slight inflammatory reaction.

THE DIAGNOSIS OF INJURIES TO THE SACRO-ILIAC ARTICULATION.*

By E. A. LEWIS, M. D.,
BROOKLYN.

The object of this paper is to call attention to a class of injuries which I believe to be not uncommon, and which I also believe are apt to be overlooked—*i. e.*, considered as contusions. I hope also to give a few symptoms which are diagnostic.

Let me call attention briefly to the anatomy of this articulation.

The ligaments which hold the sacrum and ilium together are simply anterior and posterior sacro-iliac. The anterior, thin ligamentous bands stretching from one bone to another; the posterior, thicker and more numerous fibers, making a strong ligament.

These ligaments proper are supplemented by the greater and lesser sacro-sciatic, and by the lumbo-sacral and ilio-lumbar from the transverse process of the last lumbar vertebra. Thus the articulation, as you here see it, seems to be, and is, a very strong one. Nevertheless, when force is applied to it in certain directions, it may not require a very great amount of violence to cause a separation, or partial separation, of the bones. I do not mean a displacement causing deformity, for this would require very great violence, owing to the way the sacrum is wedged in at the base of the spine; but I do mean an interference with the integrity of the articulation, giving rise to certain symptoms which differ from those of simple contusion, or may be associated with them. Two cases have come under my observation within the last two or three years which illustrate the particular points to which I wish to call attention.

On October 20, 1882, Thomas O., aged thirty-six, a strong man, in perfect health, was riding a spirited horse. The animal was restive, and, in prancing, threw the rider with some force forward, so that he struck astride the sharp shoulders of the horse, and they acted as a wedge between the nates. Mr. O. felt injured, and immediately dismounted, but found he could

* Read before the Medical Society of the County of Kings, November 17, 1885.

not stand. He was removed to his home in an ambulance. Examination showed no contusion whatever. There was no interference with any function of life. The urine and fæces passed naturally. There was no paralysis of any kind. Pressure over the crest of the left ilium caused pain at the corresponding sacro-iliac articulation. There was no external evidence of displacement. The patient could lie only on his back; in this position he was perfectly comfortable. The slightest movement toward either side, by which lateral pressure was made on the pelvis, caused intolerable pain. During the third week he began to be able to turn slightly on to the right side, but for two months could not lie on the left side at all. At the expiration of one month he began to get about on crutches. For over three months he used a cane. For nearly a year he had to drag his left leg up-stairs, going up with the right leg first. At the present writing he prefers to carry a cane when walking any distance. He can not stand unsupported on his left leg. He still walks with a slight halt in his gait, caused by using the right hip joint as a pivot on which to swing the pelvis, not advancing the left leg and thigh naturally. This defect in locomotion was very apparent at first, but improved gradually. This injury seems to be permanent, and to disable the patient from any active occupation.

The second case was complicated by other serious injuries which need not occupy our time. This patient, Mr. L., was also a robust, middle-aged man, in perfect health. On April 20th of this year he was injured by a very heavy gate, under which he was rolled some distance. So far as his pelvic injury was concerned, he exhibited similar symptoms to the preceding case, *i. e.*, he could lie at ease on his back, but any attempt to turn on either side caused great pain. There appeared to be no deformity at the right sacro-iliac articulation, but pressure on the right side of the pelvis caused great pain at that point. There was no disturbance of the pelvic organs or paralysis of any kind. He laid in bed nearly a month without being able to turn on either side; then gradually could get over to the left.

At the end of two months he could lie for a very short time on his right side. He, too, began to be able to get about on crutches before he could lie at ease on either side. He walked with the same swing in his gait, depending on his left lower extremity principally for support, and using his left hip as a pivot to swing the pelvis. He experienced the same trouble in going up-stairs, being obliged to advance the left leg first and draw the right after. At the present time he is well, with the exception of the slight swing in his gait. This is improving. He can not, however, stand alone on his right leg for any length of time. He promises to make a better recovery than the first case related.

The points in diagnosis which I wish to call attention to are:

1. The history of the injury. Any force which rotates the pelvis under severe pressure, or any force which acts as a wedge between the sacrum and innominate bone, is liable to injure this sacro-iliac articulation, although it does not cause complete separation and deformity.

2. The symptoms are usually associated with those of contusion of the hip, but differ in this, that the patient must lie only on the back for a long period of time, the slightest lateral pressure on the pelvis being unbearable.

3. The patient is able to be assisted to the erect posture and to move about on crutches for some time before being able to lie on either side.

4. Many months elapse before the patient can walk with ease, and frequently the injury is permanent to the extent of rendering him unable to do any active work.

5. A peculiar affection in walking, the uninjured side being used as a pivot on which to swing the pelvis, and thus save strain on the affected articulation.

I believe there is many a man going about to-day with some difficulty who has suffered from this injury, which has been considered and called "contusion of the hip," or, perhaps, simple "injury to the hip," without further specification as to its character.

This class of injuries is apt to have a permanent defect in walking.

The articulation is never so strong as before the accident.

The points in differential diagnosis may be arranged as follows:

Contusion.	*Injury to Sacro-iliac Articulation.*
The cause is a direct blow or fall.	The cause acts as a wedge between the sacrum and os innominatum, or rotates the pelvis under severe pressure.
The thigh of the affected side will not endure passive motion.	The thigh of the affected side may be freely moved without causing pain.
Patient can turn or be turned on the side after a short time without causing much pain.	Patient can not turn or be turned on either side for a long time, and can even walk about some before being able to endure any lateral pressure on the pelvis.
Patient suffers pain in the soft parts surrounding the hip joint.	Patient suffers no pain when lying quietly on the back, unless the injury is accompanied by contusions.
Patient recovers completely in a few days, or, at most, weeks.	Patient does not recover for months, and frequently the injury is permanent.
There is apt to be ecchymosis and tenderness on pressure over the soft parts.	There is no ecchymosis, and pain on pressure is only felt when the force is applied to the bony pelvis, and then at the seat of injury—*i. e.*, the articulation.

The explanation of the symptoms of pain on lateral pressure, and the ability to stand erect and walk some before being able to lie on the side, is not difficult. A glance at the pelvis in its natural position will show. It is naturally inclined at an angle of 60° to 65°, and pressure from above downward or from below upward is made against the bony pelvic ring, and inclines to press the articular surfaces together and not to call on the ligaments at all; while lateral pressure inclines to put the ligaments on the stretch and separate the joint surfaces.

Such surgical works as I have had access to have not mentioned injuries of the character I have spoken of at all, or have passed them over with a very few words. The more serious injuries, involving fracture of the pelvis with great violence and much deformity, are the only lesions

mentioned at or in the neighborhood of this sacro-iliac articulation. The opportunity to study more cases, such as I have detailed, will, doubtless, develop more symptoms which are characteristic of this peculiar form of injury. I have seen several cases in which I suspected this injury, but the two mentioned seemed to show the prominent symptoms detailed so clearly that I thought them worth putting on record. No change was noted in the length of the lower extremities, nor was any to be expected, as the femora and hip joints were not injured.

CEREBRAL ABSCESS FROM A CRANIAL FRACTURE.*

By D. MORRIS WOOLLEY, M. D.,
BROOKLYN.

On July 30th, about 7 P. M., I was called to attend a boy, fourteen years of age, who had fallen from the roof a two-story-and-basement house. He was then in convulsions. There was considerable tumefaction over the right eye and supra-orbital portion of the frontal bone. There was no laceration of the tissues, and, from the great œdema present, it was impossible to make out any fracture. I immediately applied hot water to the feet, and gave rectal injections of whisky.

In the course of two hours I succeeded in equalizing the circulation and controlling the convulsions. The boy was finally restored to consciousness.

At this time the family physician, who is a homœopathist, came in, and I, of course, surrendered the case to him. But, had it been my case, from what I know of antiseptic surgery, I should not have hesitated in making an exploratory incision in the scalp. However, the boy was treated by this homœopathic physician for about ten days, when the family, becoming dissatisfied, again sent for me. During these ten days, I was informed, the boy had been all the time conscious, with only slight spells of delirium in the evening. It was asserted that he even went to the table and partook of meals with his usual appetite, the principal trouble being considerable pain over the eye, with much more swelling than ever.

I learned that morphine, which had been given him, greatly increased the delirium. The night previous he suffered much from pain. I found a large abscess forming and pointing just above the eye. This was poulticed with flaxseed made with hot lead-and-opium wash, and I ordered potassii bromid., grs. 10; sodii bromid., grs. 10; chloral hydratis, grs. 5, three times a day. As a substitute for morphine, I gave ext. hyoscyamus in pills of two grains each, all of which seemed to act like a charm, giving good sleep. At this time his temperature was only 100°, and he had a full pulse of about 70. His pupils contracted and freely responded to light.

The next day I found him in bed, reading a story with great interest. This I forbade. Curious to say, this boy was remarkably bright and had an excellent appetite, the only symptom being at times much pain, which increased till his temperature was about 101° and pulse 65, when I made an incision just above the eye, where the abscess seemed to be pointing. I think fully one quarter of a pint of laudable pus came out. The cavity was washed with 1-to-2,000 bichloride-of-mercury solution, a drainage-tube inserted, and the wound dressed antiseptically twice a day. The temperature fell to 99·5° F. A day or so after, another incision was made over the squamous portion of the temporal bone, when the probe detected a depression of bone and an apparent fracture. It was not until we got rid of the pus and probed extensively that anything like a depression or fracture could be made out. I then suggested to the father the necessity of trephining, but, after consulting two or three physicians, it was thought that to wait for further symptoms was the best plan.

For a few days after the incisions were made he had much less pain, and did apparently well, the pulse ranging between 60 and 70, and the temperature under 100°. But the pain returned to the region of the right eye, increasing each day with so much severity that large doses of bromide of potassium and ext. of hyoscyamus failed to produce sleep. Finally, on Saturday, at 5 P. M., August 22d, I for the first time gave, hypodermically, five minims of Magendie's solution of morphine, because for twenty-four hours he had not slept, owing to intense pain. This relieved him and produced sleep. His pulse now was 58, and temperature under 100°. All this time the boy had been intelligent, his pupils responding freely to light. Two hours afterward I found him comatose, with a temperature of 104° and a pulse of about 140. I concluded that he must now be suffering from acute encephalitis due to the burrowing of pus through some fracture of the skull.

I immediately called in Dr. Walter B. Chase, and we gave twenty grains of antipyrine hypodermically and ten grains by the mouth. In less than one hour the temperature fell to about 102°. Next morning the temperature was 100°. In the evening it rose to 102°. At this time we held a consultation, calling in Dr. J. H. Hunt. We decided to trephine on the following morning. We gave chloroform for anæsthesia because least liable to cerebral excitement. After making an incision and dissecting up the scalp we found a stellate fracture of the right frontal bone just above the orbit. In the center of this fracture was a triangular piece of loose bone with one of the angles penetrating the substance of the brain, causing a deep abscess into which you could put your finger. We took this bone out and elevated a portion of the rest. About five hours later the temperature went up to 104°, and it was again shortly afterward reduced to 102° by antipyrine. The next morning, which was Tuesday, the temperature remained the same. In the afternoon there was an elevation to 103°. Gave antipyrine, with some slight return of consciousness, but pupils somewhat dilated. Wednesday morning the temperature was down to 101°, with a good pulse of about 100. In the evening the temperatute went up to 102°, with contracted pupils. The next morning it went down to 100·75°. In the evening there was another marked elevation to 104·25°. At this time there seemed a marked change for the worse; the pupils were more dilated than ever, the breathing was heavy, the pulse 140 and very weak, and the coma more profound.

I injected twenty grains of antipyrine hypodermically, and gave ten grains by the mouth. Shortly after, the temperature fell to 101·5°. He regained some consciousness, speaking in monosyllables. About midnight the temperature was taken by the nurse and found to be slightly subnormal.

On Friday morning the temperature was 101·5°, the pulse good and full, and I was told that the boy recognized those around him and was at times quite conscious. I went again to see him at 2 P. M., and the temperature was up to 104°. Again I gave twenty grains of antipyrine, which by the evening had brought it down to 101·25°, with a good, full pulse.

On Saturday morning the temperature and pulse were the same. In fact, there was no change that day except his being at times slightly conscious, having said to his sister, when annoyed, "Get out!" No antipyrine was required this day. The case now seemed more hopeful—in a word, he was better than any time since the operation, and we felt that nature was going to

* Read before the Brooklyn Pathological Society, October 8, 1885.

bring the boy through. But Sunday told a different tale. That morning the temperature was 104°, with a full, rapid pulse. Twenty grains of antipyrine failed to produce any effect, and by evening the fever was raging at 104·5°, with a pulse of 142.

I gave 3 ss. of antipyrine and applied ice to the wrist. Here I would say that the ice-bag had been continuously applied to the great vessels of the neck ever since the commencing night of the high fever. However, we again, in a few hours, succeeded in bringing the temperature down to 101°, the pupils contracting and responding to light.

On Monday morning at eight o'clock the temperature was 102·75°. I undressed and washed out the wound as usual with 1-to-2,000 bichloride-of-mercury solution. During the last two or three days there seemed to have been more discharge of pus than usual, but presenting a very healthy appearance.

In the evening the temperature was 102·6°. He answered "Yes" to the question "Do you see?" On Tuesday morning the temperature was 103·25°, with a full pulse of 140. Gave twenty grains more of antipyrine. That evening the temperature and pulse were about the same. I repeated the same quantity of antipyrine and reapplied ice to the wrist. I asked him if he felt any pain. He faintly replied, "My eye hurts."

Wednesday morning the temperature was 103·6°. Gave twenty grains of antipyrine. In the evening the temperature went up to 104·8°, the highest point yet reached. Again gave twenty grains more of antipyrine, and the temperature, in less than two hours, fell to 102°, and by twelve o'clock that night it was 101°.

Thursday morning, temperature 103·5°. Left foot cold, while the rest of the body is warm. Since last night, for the first time, there has been difficulty in swallowing. There is a tremor to the pulse. When the left leg is touched, it causes some distortion of the facial muscles. There is now a greater change and a more anæmic condition of countenance. It looks as though the vital centers were being disturbed. In the evening the temperature was 103·25°. Gave twenty grains of antipyrine, without any effect.

On Friday morning there was still a greater change for the worse. The countenance was that of the Hippocratic expression, the temperature again reaching 105·25°. It did not seem that he could last over two hours, yet his heart was beating well, and, with the vitality present, he might live till night. He died that afternoon about six o'clock. The next day Dr. Hunt and I held an autopsy, but, much to our surprise, found no meningitis except a localized portion around the point of fracture. We found no other changes except a deep abscess which had broken into the right lateral ventricle.

The conclusion which may be drawn from this case is, that this abscess had commenced to form immediately after the perforation of the dura mater, and the irritation caused by the triangular piece of bone, and that perhaps the high fever and sudden coma came after the rupture in the ventricle.

I think there is also one important lesson which may be drawn, and that is, that we are apt to be too conservative at times. It strikes me that, without antiseptic precautions, very little may be lost by trephining while a great deal may be gained. In all probability, had an operation been made immediately after the accident, the chances of the boy's life would have been greatly enhanced.

The Department of Public Charities and Correction of the city of New York has been allowed $1,537,300 to cover the expenses for the coming year.

Book Notices.

Contributions to the Topographical and Sectional Anatomy of the Female Pelvis. By D. Berry Hart, M. D., F. R. C. P. E., Lecturer on Midwifery and Diseases of Women, School of Medicine, Edinburgh, etc. Edinburgh and London: W. & A. K. Johnston, 1885. 4to, pp. 8, xii plates.

We have several times been gratified by being able to speak in commendation of Dr. Hart's researches in pelvic anatomy, and these beautiful plates call no less for praise than the author's previous publications. They relate for the most part to sections of frozen cadavers. The descriptive text, brief as it is, deserves careful reading, preferably in connection with Dr. Hart's other contributions to the anatomy of the pelvis.

Contributions to Surgery and Medicine. Part I. Intestinal Disease and Obstruction. London: H. K. Lewis. Pp. 284.

The title of this work hardly conveys an adequate idea of its scope and contents. It is an essay by Hugh Owen Thomas on the intestinal lesions of typhoid fever and the milder forms of obstruction, with particular reference to treatment. With operative procedures it has little or nothing to do, and the therapeutic methods may be summed up in two words—rest and starvation. The action of opium and belladonna is carefully studied, and the indications for their use are given. All active methods of manipulation, purgatives, enemata, kneading, etc., are condemned.

The work has been carefully done, and shows study. The latter half of the book is made up of a large number of histories of cases, with appropriate comments.

Correspondence.

LETTER FROM WASHINGTON.

The American Public Health Association.—The Inspection on the Canadian Frontier.—Proposed Sanitary Legislation.—The Cholera in Japan.

Washington, *December 14, 1885.*

Since my last the city has been enlivened by the presence of the American Public Health Association. The President, Senator Harris, and Representative Beach were expected to be present at the opening, but the President only sent a letter, and the other gentlemen had other engagements. The meeting, however, was successful, and, although perhaps there were those little elements of discord so often present at gatherings such as this, where every health officer has some special measure of his own to put through, yet, as a whole, it was harmonious and creditable to all concerned. The election of Dr. H. P. Walcott, of Cambridge, as president, was a deserved compliment to a distinguished health officer, and broke up the pestiferous custom of perpetually electing the vice-president, without any regard to

special fitness. No man has been more thoroughly identified with Southern sanitary matters than Dr. G. B. Thornton, of Memphis, who was elected first vice-president, and Canada was appropriately recognized by naming Toronto as the next place of meeting, and a Canadian as second vice-president.

The special features of the meeting were the papers read and the social pleasures. Among the interesting papers, those of Dr. Joseph Holt, of New Orleans, Dr. O. W. Wight, of Detroit, Dr. Armstrong, of the Marine-Hospital Service, Dr. Hartwell, of the Johns Hopkins University, and Dr. John Morris attracted unusual attention. Dr. Holt is an orator as well as an efficient health officer, and the reading of his paper was accompanied by round after round of applause. Dr. Wight maintained that the disinfection of the abominable sewers of Detroit by burning sulphur at each man-hole had been followed by a great reduction in the death-rate from diphtheria and scarlet fever, and that the sulphur fumes speedily found out all the defective traps in houses; and many amusing instances were given of its effectiveness. Dr. Hartwell's paper was on the method of physical training adopted in Germany to secure the *mens sana in corpore sano*, and the methods of the "Turners" as well as those of the gymnasium professors were fully explained. There is no doubt that the time is coming when the "pale-faced, stoop-shouldered student" will be only a reminiscence. There is no longer any reason why intellectuality should be regarded as a necessary sequence of chronic dyspepsia and mal-assimilation. Dr. Morris's paper dealt strongly with the necessity for crematories everywhere, in order to insure proper facilities for cremation of the dead. He cited the evils of the existing practice of inhumation near our cities so forcibly that the "Republican" the next morning editorially spoke of the water drank by the Philadelphians as a product of the rain-fall into the Schuylkill mixed with a large percentage of the distillate from the bones of their ancestors.

The trip to Mount Vernon and the oyster roast were very successful.

The Marine-Hospital Bureau has ordered the discontinuance of the inspection at the International and Suspension Bridges, in accordance with the request of the State Board of Health of New York. The maritime inspections at the lake ports have been discontinued owing to the closure of navigation and the efficient work now being done by the health authorities of Ontario.

Senator Palmer has reintroduced the bill prepared by Dr. Wight, of Detroit, last year, providing for a Commissioner of Health for the United States.

Senator Eustis, of Louisiana, has introduced into the Senate the bill prepared by Dr. Holt to provide "for the appointment of a commission to investigate the declared discovery of inoculation of yellow fever, and protection so afforded against that disease." The bill contemplates the appointment of three commissioners, who shall proceed to Brazil, investigate Freire's alleged discoveries, and report thereon. Thirty thousand dollars are to be provided for the expenses of the commissioners. Senator Harris, of Tennessee, has reintroduced the bill to rehabilitate the National Board of Health and restore its former functions, which expired in June, 1883. This Senator, it will be remembered, is the chairman of the Public Health Committee of the Senate, or, as it is somewhat euphemistically styled, the "Select Committee to Investigate the Introduction and Spread of Epidemic Diseases." Speaker Carlisle has not yet appointed the Public Health Committee of the House, but it is presumed that he will do so this week, and that the Hon. Lewis Beach, of New York, will be appointed.

Press dispatches, confirmed by the Department of State, announce the increase of cholera in Hiogo and Osaka, Japan.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & Co.
Edited by FRANK P. FOSTER, M. D.
NEW YORK, SATURDAY, DECEMBER 26, 1885.

THE ALUMNI OF THE WOMAN'S HOSPITAL.

It is always a good thing for the graduates of an educationa, institution to organize themselves into an alumni associationl even if for no other reason than that it serves to keep alive the *esprit de corps* that readily takes root among young men, but is apt to droop under the heat of the actual conflict of life unless nurtured and sustained by some specially favoring circumstances. But there are other reasons why such organizations are to be commended, not the least of which is the influence that they are more and more getting to be able to exert in strengthening the hands of the managers of the institution, whatever it may chance to be, and, to some extent, in shaping its policy. It is only within a very few years that associations of the alumni of medical colleges have aspired to much more than social objects in this country, but now they may fairly be said to have lifted themselves far above that plane, as witness the laboratory, the annual prize, and the Cartwright lectures, established by the exertions of the Alumni Association of the College of Physicians and Surgeons. That is one of our oldest colleges, and it is but natural that its alumni should have made their association conspicuous among like organizations; but the very creditable showing that has been made by a number of other similar bodies argues their early achievement of commensurate importance.

When we speak of educational institutions it does not follow that we have in mind exclusively those which furnish didactic instruction in the various branches of medicine, and round it off by conferring the doctorate. On the contrary, nothing could be more truly educational—more drawing out—than the training that the young graduate gets during his term of service on the house staff of a hospital. Moreover, the bond of personal sympathy is far closer between the few to whom such a service is necessarily restricted than it can be among the more miscellaneous and far more numerous students of a college. We presume it may therefore be inferred that the rarity of associations of hospital alumni is due to the idea that numbers are necessary to success, but we are confident that a hospital alumni association which has recently been formed is destined to an amount of success that will speedily disabuse the profession of that notion, especially as the hospital is a comparatively new one and also a special one, and therefore subject to the full drawbacks that may be supposed to attach to the formation of successful associations of hospital alumni.

We refer to a gynæcological society composed entirely of gentlemen who have served on the house staff of the Woman's Hospital, in New York—a society that is now well organized and started on its career. Necessarily its members are for the most part young men, but many of them are already known

wherever gynæcological literature penetrates; and that it should have been able, in the few years of its existence, to rear a body of alumni so promising and so favorably known is not the least of the laurels to which the pioneer woman's hospital of the world may lay claim. The programme arranged for the first meeting of the new society seems to us exceedingly creditable, and we do not doubt that the proceedings at the annual meetings which are to follow will prove of equal value and importance. The formation of the society is a good move, and we wish the organization all possible success.

MINOR PARAGRAPHS.

THE "MEDICAL TIMES AND GAZETTE," OF LONDON.

It is rumored that this most estimable journal will cease to be published with the close of the present year. This will be unwelcome news for those who have been accustomed to peruse its columns, especially during the two years that it has been under the editorial management of Dr. Philpot. The "Times and Gazette" was always a valuable journal, but Dr. Philpot has made it, so far as the editorial columns are concerned, by far the most readable of the London weeklies. We shall sorely miss it from our exchanges.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 22, 1885:

DISEASES.	Week ending Dec. 15.		Week ending Dec. 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	0	5	0
Typhoid fever	16	5	19	5
Scarlet fever	50	5	52	21
Cerebro-spinal meningitis	3	3	1	1
Measles	6	2	14	1
Diphtheria	75	33	104	41
Small-pox	5	1	12	1

Pasteur's American Patients.—News has been received that the Newark children who were lately sent to Paris, in order that they might undergo proteetive inoculation against rabies at the hands of M. Pasteur, have arrived in good condition and have been subjected to the early inoculations of the series.

Small-pox in New York and Brooklyn, as well as in a number of other places, although not verging on epidemic prevalence, is coming to light far oftener than it is comfortable to contemplate. It is reported that the number of patients now in the Flatbush Hospital is greater than at any other time during the last three years.

Diphtheria in Ontario.—The schools are reported to have been closed in Delaware, Ont., on account of the prevalenec of diphtheria, and it is said that for the same reason certain Sunday-school entertainments which were to have eome off at about this time have been postponed.

A Conviction for Criminal Abortion has been obtained in Cleveland, Ohio, and it is satisfactory to learn that the heaviest penalty possible, imprisonment for seven years, has been imposed on the prisoner.

An Impostor.—Dr. Silas C. Blaisdell, of Brooklyn, E. D., writes to us as follows: "F. W. Cowan, a graduate of the University of last year, has been visiting various physicians and obtaining money on false pretenses, representing himself as having been robbed, etc., while visiting the city, purporting to come from Newark, N. Y. Dr. Cooper, clerk of the University, has in his possession several cards from physicians already swindled by this impostor, and would like the card of any other having a similar experience with this disgrace to the medical profession."

The Death of Dr. John S. Heard, of Newburg, N. Y., took place on Friday, the 18th inst. The deceased was a graduate of the College of Physicians and Surgeons, and formerly practiced medicine in New York. After taking his medical degree he served on the house staff of the New York Hospital. At the time of his death he was seventy years old.

The Death of Dr. Isaac G. Collins, of Sing Sing, N. Y., occurred on the same day. He was a graduate of the Albany Medical College, and had been president of the Medical Society of the County of Westchester. He was fifty-three years old.

Society Meetings for the Coming Week:

Tuesday, *December 29th:* Boston Society of Medical Sciences (private).

Wednesday, *December 30th:* Auburn, N. Y., City Medical Association; Berkshire District, Mass., Medical Society (Pittsfield).

Thursday, *December 31st:* Cumberland County, Me., Medical Society (Portland).

Friday, *January 1st:* Practitioners' Society of New York (private).

Saturday, *January 2d:* Clinical Society of the New York Post-Graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

OBITUARY.

John Christopher Draper, M. D., LL. D.—Professor Draper, a son of the late Professor John W. Draper, died, after a brief illness, on Sunday, the 20th inst., in the fifty-first year of his age. He was a native of Virginia, but was educated in New York, having been graduated from the academical department of the University of the City of New York, and subsequently from the medical department of the same institution. When he had obtained his medical degree, which he did in 1857, he served on the house staff of Bellevue Hospital, and was soon afterward made professor of analytical chemistry in the University of the City of New York. For three years, from 1860 to 1863, he served also as professor of chemistry in the Cooper Institute. Since 1863 he has been the professor of natural history and physiology in the College of the City of New York, and since 1866 professor of chemistry in the medical department of the University of the City of New York. He received the degree of LL. D. from Trinity College in 1873.

Albert Holmes Smith, M. D., of Philadelphia.—Dr. Smith, whose untimely death we briefly mentioned last week, was a native of Philadelphia, where he received his education and afterward practiced his profession. He was a graduate of both the academical and the medical departments of the University of Pennsylvania. After taking his medical degree he became resident physician to the Frankford Asylum for the Insane, in which capacity he served for a year and a half, and then became a member of the house staff of the Pennsylvania Hospital. He began private practice in 1859, and in the same year he was made an assistant physician to the Philadelphia Lying-in Charity. In 1862 he was appointed accoucheur to the Philadelphia Hospital, and the following year physician and lecturer to the Lying-in Charity. He was one of the founders of the American Gynæcological Society, of which he was chosen president

in 1883. He was also one of the founders of the Obstetrical Society of Philadelphia, a fellow of the College of Physicians, and a member of the Philadelphia County Medical Society and of the Philadelphia Pathological Society.

Dr. Smith was an accomplished obstetrician and an earnest and lucid teacher. He was a man of fine physique, and his conscientiousness as well as his amiability raised him high in the esteem of his professional brethren and of the community in which he lived. For more than two years before his death it was evident that his health was hopelessly shattered, and that period was marked by great suffering, which he bore with patient resignation. He was in his fifty-first year at the time of his death.

Letters to the Editor.

THE CHLORIDE-OF-SILVER CELL *VS.* THE GRENET CELL.—A REPLY TO DR. RANNEY.

BROOKLYN, *December 15, 1885.*

To the Editor of the New York Medical Journal:

SIR: In your issue of the 28th ultimo is contained an article by Dr. Ranney upon the worth of the chloride-of-silver battery, which I had recommended so warmly in your Journal of July 18th. Dr. Ranney intimates that he is impelled to write upon the subject because of a feeling of "duty to correct some statements made in that article" (mine) "apparently on insufficient information." I propose, in reply, to make plain that, from the beginning to the end of Dr. Ranney's letter, there is scarcely a statement that is not made on insufficient information, and this not *apparently*, but *indubitably* so. Indeed, so numerous and so crass are the incorrect statements that one is almost led to doubt whether Dr. Ranney has ever seen the battery on which he passes judgment—a doubt to which corroboration is lent by the fact, stated to me by the manufacturer, that Dr. Ranney would not even let him—the maker—show him the instrument.

Dr. Ranney says: "The chloride-of-silver-and-zinc element as the basis of a battery is not new." If the doctor will turn to my article, he will be happy to ascertain that I never said it was. On the contrary, I expressly spoke of this type of battery as being made by Gaiffe, of Paris. I shall also have occasion, in this letter, to convince Dr. Ranney of the worth of one made many years ago by De la Rue.

"Dr. Gray need not have written to foreign countries (as he states in his article that he has done) to obtain much valuable information respecting its rise and fall. The 'chloride-of-silver' battery presented to the profession some years since by the Western Electric Company is practically the same as the one Dr. Gray now extols. True, it had glass cups in place of rubber ones (which cost more), and it lacked some other of the mechanical features described by Dr. Gray, although the latter are but copies or slight modifications of identical devices employed by other manufacturers of this city and Europe. Its excitant was the same, the elements were the same, the cell was practically the same, and the battery was light and easy to handle (the only claim, in my opinion, which it ever had to 'universal recognition'). The battery was sold extensively at first by a reputable firm in this city, and probably equally so elsewhere. This firm finally declined to continue selling it, and I am informed that the Western Electric Company has since discontinued its manufacture. So much for the history of the 'chloride-of-silver battery' in this country from a practical standpoint."

No, Dr. Ranney, this is not all of the history; this letter will carry it up to date:

"WESTERN ELECTRIC COMPANY,
"NEW YORK, *Dec. 1, 1885.*

"DEAR SIR: In regard to Dr. Ranney's article in the "Medical Journal," we would say that he is correct in the statement that we are not especially pushing the sale of the chloride-of-silver battery as a medical battery. The reason he assigns, however, is incorrect. The true reason is that we are not pushing in this city the sale of any medical batteries, because it requires more special attention than we are prepared to give it. We are, however, selling this battery very extensively *as a testing battery, its constancy and durability especially recommending it to well-posted electricians for that purpose.**

"Yours truly,
"WESTERN ELECTRIC CO."

As to the mechanical features of the battery described by me being mere copies or modifications of others, it is only necessary to say that all the details of construction are contained in my article; that Dr. Ranney could have indicated to me wherein they were copies or modifications; that the Patent-Office has regarded them as sufficiently original to grant the maker a strong patent; that the battery as thus made has given greater satisfaction than any previous one of the same kind.

Although it is true that the elements of this battery are the same as in others that have been made, the excitant is not the same. It is here the sulphate of zinc, while in the others it has been some of the soluble chlorides. As this peculiar excitant bears an important relation to the internal resistance, as well as to the durability of the elements, it follows that it is not correct to say, as Dr. Ranney does, that "the cell is practically the same."

"Dr. Gray admits that Mr. Schoth, of Europe, has thus far failed to make a satisfactory battery with this form of cell."

I did not *admit* it—I *stated* it, and very distinctly. I fail to see that this fact has any other importance than that a man in London failed to do what a man in Paris and another in New York succeeded in doing.

"Dr. Gray has tried his own battery but a few months; yet, because it works and is light, he gives it his unqualified indorsement. Is not the conclusion on its face rather a hasty one?"

That depends very largely on who puts on the face. I think that Dr. Ranney has somewhat altered its complexion. We can obtain some knowledge of the original lineaments by the following reproduction of what I actually did say: "The instrument which, as I have already said, I have had in daily use for *some five months, and which has many days been jolted about in my carriage over rough city streets for five or six hours at a time, has maintained its current unimpaired in quantity or quality.*"

Dr. Ranney goes on to inform us that "this type of cell has a low electro-motive force, and generates but a small quantity in the battery Dr. Gray describes."

First, as to the electro-motive force. Niandet—who, as Dr. Ranney will probably admit, is an authority in electrical matters—puts the electro-motive force of the Daniell cell—which, as Dr. Ranney will again admit, is usually taken as a standard—at figures varying slightly from 1 volt to 1·079 volt, according to the density of the solutions used. In the same table, De la Rue's chloride-of-silver battery is given at 1·051 volt. De Watteville—who, as Dr. Ranney will probably not deny, is good authority—states that the Gaiffe chloride-of-silver cell has an electro-motive force "about the same as the Daniell's, 1·03 volt." It is well known to electricians that, in 1873, Mr. Latimer Clark communicated to the Royal Society an account of a cell so ingeniously and delicately constructed that its electro-motive force would not for months show a difference of more than $\frac{1}{1000}$ part

* The italics are mine.

of the whole electro-motive force, and even this infinitesimal difference could be accounted for by an accidental difference of temperature. This would seem to be a good enough standard for any reasonable man. It so happens that Mr. Hamilton, of the Western Union Telegraph Company, possesses some of these Latimer Clark Standard Cells, and the chloride-of-silver cell which I described in my article has been compared with them and found to have an electro-motive of 1·03 +, being thus practically the same as these exquisite Latimer Clark cells.

Second, as to the quantity. An elementary application of Ohm's law would show Dr. Ranney that, through such high resistances as are usually those of the human body, the quantity of electricity which will be carried by any battery will depend very largely upon the electro-motive force employed, and that the size of the plates and the capacity to generate large quantities of electricity have no practical bearing on the result. Only a certain quantity of electricity can be used about the human body, and that quantity is not large, the maximum being about forty milliampères. In the construction of batteries for medical purposes, there is seldom any difficulty about obtaining sufficient quantity, the chief obstacles being the weight, the constancy, and the liability to spill.

We are furthermore told that "the elements are costly, and are not regarded by well-posted electricians as possessing the durability Dr. Gray claims for them. It is true that the silver can be reclaimed (when the fluid is saved after the elements are consumed and subjected to certain chemical processes), but few physicians would go to that trouble for the purpose of saving a few dollars. Dr. Gray estimates that it will cost 'about $8 per year' for repairs. Even at this very low estimate, the battery becomes decidedly expensive. He fails, moreover, to state the first cost of the instrument—so that comparison on that score with the cost of other batteries made by reputable manufacturers is impossible."

1. As to cost. The cost of a fifty-cell battery of this kind, with electrodes and pole-changer, is $65, being about fifteen to twenty dollars more than that of other batteries of the same power. But, in my opinion, this additional cost is more than repaid by the durability, the infrequent recharging, the light weight, and the value of the silver ultimately reclaimed—as I shall soon show—in the chloride-of-silver cells. One might suppose that the same "few physicians" who would disdain going to the "trouble for the purpose of saving a few dollars" would also disdain the additional cost at the outset.

Dr. Ranney states that the silver is reclaimed from the fluid by certain chemical processes. As a matter of fact, the silver is not reclaimed from the solution, but remains in a block of refined metal of exactly the shape into which the chloride of silver was originally cast, and this block can be removed readily by any one with a pair of pinchers, together with the wire which holds it. Does this not make it impossible to avoid the conclusion that Dr. Ranney is grossly ignorant of the cell which he attacks? I have had the silver so remaining in a single cell weighed, and its actual value is fifteen cents, which for fifty cells would be $7.50—about enough to pay for renewal of all these cells after a year or eighteen months' service!

2. As to "well-posted" electricians not agreeing with me as to the durability of the cell.

Gordon, in his standard work,* has a quotation from De la Rue which states that he had been for three years working a battery made of the chloride-of-silver elements "with, practically, a constant electro-motive force."

De Watteville, in his equally standard work on electro-therapeutics, says: * "I am not aware of any other battery which combines to the same extent durability, portability, and efficiency."

Messrs. E. S. Greely & Co., successors to the firm of L. G. Tillotson & Co., of New York, whom Dr. Ranney will probably recognize as well-known manufacturers of electrical instruments, have adopted the battery described by me not only for medical uses, but also as a standard testing battery for such service as depends specially upon constancy and durability. This firm is even arranging to issue a special circular on the subject.

Professor A. K. Eaton, whom all "well-posted electricians" know as a manufacturer of electrical measuring instruments, employs this same battery in "standardizing" or calibrating his meters.

Messrs. George Tiemann & Co. are arranging to keep this battery in stock, and are preparing circulars for a wide advertisement of its merits.

The opinion of the Western Electric Company is contained in the letter given above.

I do not deem it necessary to multiply similar opinions.

"In the third place, great stress is laid by Dr. Gray upon the light weight of the battery (9 to 12 pounds). Personally, I fail to see why a physician who owns a buggy and horse need to care much if a few pounds of weight are or are not dispensed with, provided he can carry the machine easily from the carriage to the house of each patient without assistance."

In the first quotation which I have made above from Dr. Ranney he says, speaking of the battery made by the Western Electric Company, that its lightness and easiness to handle constituted its only claim, *in his opinion*, to "universal recognition." He thus expressed his opinion that a battery might have no other claim than lightness and easiness to handle, and yet be entitled to "universal recognition." Some thirty lines further on, he can not see why lightness—one half of the claim to "universal recognition"—should make any difference! It would thus seem that not only does Dr. Ranney not know the chloride-of-silver cell, but that he has only a bowing acquaintance with his own opinions. But, although the first of these two opinions refutes the last, I would say in addition that, although I am rather of muscular build, there is considerable difference, in my opinion, between the 9 to 12 pounds of the chloride-of-silver battery and the 25 to 30 pounds which other batteries of like size may weigh. A battery that can be carried lightly in the hand is usually preferred by the disinterested to one that causes a temporary lateral curvature of one's vertebral column.

For the Grenet cell Dr. Ranney claims many advantages. Let us examine them in detail.

1. Cheapness of construction.

The Grenet cell *is* cheaper, as I have said; how much cheaper, I do not need to repeat.

2. "A fluid which can be renewed when required at a cost of a few cents."

I have a battery containing 35 Grenet cells, and the actual cost of the necessary fluid for all of them is 75 cents—not a few cents. As this needs to be renewed at least every month, sometimes every two weeks, the annual cost of renewal would be $9 and over, as against $8, after 18 months' service, with the silver cells.

3. "A cell whose elements last a long time, and cost about ten cents each to replace when they at last are consumed by the fluid."

If Dr. Ranney used his Grenet cells much he would find, as I have, that the elements will last about three or four months.

* "A Physical Treatise on Electricity and Magnetism," vol. i, p. 216.

* "Medical Electricity," New York, 1884, p. 61.

4. "A high electro-motive force."

The electro-motive force of the Grenet cell is 1·7 volt. But this is only when the cell is freshly charged, and by work this gradually diminishes until it becomes too low for use. The chloride-of-silver cell, as we have seen, is 1·03 volt, and we have also seen that it is remarkably constant.

5. "A considerable quantity of electricity."

It is not necessary to repeat what we have already said about Ohm's law.

6. "An easy way of overcoming polarization when the battery is in use."

Dr. Ranney seems to have made a new discovery about the Grenet cell. I frankly admit that I do not know what he means by this.

7. "A clean instrument, which, when properly made, will not spill the fluid."

This, when piously examined, is the most remarkable statement of all, for the double reason that it furnishes additional proof, if any were needed, that Dr. Ranney has never seen the chloride-of-silver cell which he attacks, and also because it provokes grave doubt as to whether he has ever closely examined the Grenet cell which he advocates. The chloride-of-silver cell which I described is a glass or rubber bottle, into which is screwed a rubber top. It is therefore tighter than a corked bottle. Into this bottle are put the fluid and the elements, and the wires coming from the elements come through the rubber top. This cell, therefore, does not spill, as Dr. Ranney evidently infers. On the other hand, the Grenet cell is a jar, on the top of which is loosely laid a plate, this plate holding the elements. It can very easily spill. In order to prevent it spilling, some batteries composed of it are so made that the elements can be hoisted up, or the jars can be lowered, and a rubber-covered board or gutta-percha plate is thrust in between the elements and jars thus separated, and held in place by a spring. This board or plate—the so-called "hydrostat"—is, of course, a part of the *battery*, not of the *cell;* and, as can be seen at a glance, is cumbrous as compared with the neat compactness of the silver cell.

8. "The ability to select the cells employed from any part of the battery."

Still more proof that Dr. Ranney has never seen the battery which I described, or else he would have known that to its plates are attached two wires terminating in hollow plugs, and that by these plugs one can select any cells whatsoever.

9. "A simplicity of construction which admits of repair by the physician himself, if he possesses a screw-driver and a pair of pinchers."

To this list should be added a sweet and equable temper, total abstinence from profanity, mechanical ardor sufficient to enjoy a half-hour to an hour's plying of the aforesaid screw-driver and pinchers in the midst of one's office hour or just when one is sallying out on his rounds, or at other opportune moments of life, and also philosophy enough to find amusement in the occasional necessity for sending the battery to an electrical mechanic in spite of pinchers and screw-driver.

Since writing my article in July I have had four months' additional trial of the particular battery which I described, making nine months in all. The battery was then accidentally turned upside down for several hours, and thus injured. The cells were taken out and carefully examined, *and it was found that they were only used up to about one half of their capacity.* The battery would, therefore, have run eighteen months had it not been for the accident.

Nor is my experience a single one. Dr. J. B. Hunter, of New York, now uses this battery exclusively for his work in practice and at the Woman's Hospital, and has just ordered a third one. Dr. J. J. Putnam, of Boston, has been using one for six months, and states that he is well pleased with it. Dr. B. Sachs, of New York, writes me: "I have had the new chloride-of-silver battery in almost daily use for more than five months, and I am extremely well pleased with it. I find that it fulfills all that Mr. Barrett claims for it. It is durable, very easy to manage (if one knows anything at all about batteries), and portable. As I am in the habit of using an absolute galvanometer in all applications, whether for diagnostic or therapeutic purposes, I can safely say that the electro-motive force of these cells has not sensibly diminished in the course of five months." Dr. Charles K. Mills, Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic, reports that he has used the battery for several months with great satisfaction. "Its portability," he writes, "greater than that of any other battery of equal current strength, the absence of corrosion, and the little trouble required in its management, are features of excellence which will serve to make it deservedly popular with specialists and general practitioners."

"Some months ago Dr. Brown, of this city, exhibited, at a meeting of the Clinical Society of the New York Post-Graduate Medical School, the very battery which Dr. Gray now presents as novel. The remarks of Dr. Brown were published, without the cut, in the 'New York Medical Journal' in February, 1885. If I am not mistaken, Dr. Brown had been instrumental in calling the attention of the manufacturer to several of its best features."

The maker informs me that the "several of its best features" suggested by Dr. Brown were—that the handle should be made larger! As the battery was shown to Dr. Brown, as well as to many other gentlemen, after it had been made at my suggestion, I have never understood that Dr. Brown has made any claim to priority in the matter. Dr. Ranney will be glad to learn, however, that, at the time Dr. Brown showed the battery, he incidentally remarked that "this little battery was the best portable galvanic battery he knew of."

"In closing, I would say that the sentence in Dr. Gray's article which impugns the many advantages claimed for the Grenet cell, both by myself and others, for a portable galvanic apparatus, is not in accord (as far as I can learn) with the experience of thousands who are to-day using this form of cell in Europe and this country. It seems to give universal satisfaction when properly managed and cared for."

These remarks are answered, I think, by what I have already said.

I charge, therefore, that Dr. Ranney was entirely ignorant of the chloride-of-silver battery upon which he attempts to pass judgment, because—

1. He did not know what the excitant of the cell was.

2. He did not know that any of its cells could be selected at will.

3. He had not the remotest idea of how the silver was reclaimed.

4. He did not know what the worth of the silver was when reclaimed.

5. He knew nothing of the cell's durability.

6. He did not know that it was impossible to spill the contents of the cell unless the cell were broken.

Incredible as it may seem, Dr. Ranney went so far as to write this: "If I should state in the commencement that I have intentionally omitted this form of cell from the list of those which I have depicted and recommended in my forthcoming work upon 'Electricity in Medicine,' and that I have done so for good and sufficient reason, I must either admit myself to be unacquainted with the progress lately made in electrical de-

vices, or I must prove the soundness of my convictions. I prefer to attempt the latter."

I leave it to my readers to determine whether the "attempt" has been successful. If not, taking Dr. Ranney at his own word—what follows?

I desire to return my thanks to Dr. Ranney for thus affording me a further opportunity of calling the attention of the profession to what I consider to be by all odds the best portable battery as yet made for medical purposes.

Yours very truly,

Landon Carter Gray.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of December 8, 1885.

The President, Dr. Charles McBurney, in the Chair.

Supra-pubic Lithotomy; Suture of the Bladder-wound; Primary Union.—Dr. Pilcher presented a man, twenty-one years of age, upon whom, two weeks ago that day, he had operated for the removal of stone from the bladder by the supra-pubic method, as perfected by Petersen, of Kiel. The patient had suffered from symptoms of stone about nine years. After etherization, a rubber ball having been introduced into the rectum, it was distended with about ten ounces of water, after which nine ounces of a warm solution of boric acid were injected into the bladder through a soft-rubber catheter. The result was to cause a very marked protuberance of the bladder above the pubes, and to make exposure of its antero-superior wall by incision above the symphysis pubis remarkably easy. The wall of the bladder having been exposed, he followed the suggestion of von Antal of making an incision first through the muscular wall of a beveled shape, so as to increase the width of the fresh surfaces afterward to be united by suture. This step having been accomplished without serious inconvenience, the blue color of the mucous membrane of the bladder could be plainly seen by all present in the operating-room of the Post-Graduate Medical School, where the operation was performed. Upon the incision into the bladder being completed, the stone was seized and removed without difficulty. It was of moderate size, weighing 207 grains in its dry state, and was composed of a nucleus of uric acid with an external layer of oxalate of lime, principally, with some triple phosphates. The ease with which the interior of the bladder could be inspected, after removal of the stone, was particularly noteworthy. The posterior wall was clearly visible, and the whole anterior wall was easy of exploration. The catheter, through which the preliminary injection of boric-acid solution had been made, was left *in situ*, to insure continuous drainage of the urine; the wound in the bladder was closed at seven or eight points by fine silk sutures passing through only the muscular and submucous layers. The suprajacent musculotendinous layer was then closed by a running catgut suture, and the subcutaneous tissue was brought together and supported with three hare-lip pins, and finally a superficial line of sutures was placed through the integumental wound. A little cotton, sprinkled with iodoform, was laid upon the wound, and the man was put to bed and did perfectly well. The catheter was removed on the ninth day, and the pins were taken out the day following. On the eleventh day the man went to his home, permanent primary union throughout the whole extent of the wound having taken place without unpleasant symptoms of any kind. It was now fourteen days since the operation.

About fifteen months ago Dr. Pilcher had advised with regard to an operation in the case of a child ten or eleven years of age, in whom, according to his wish, the supra-pubic method was likewise adopted. The operation was performed by Dr. McPhail at the Brooklyn Orphan Asylum. In that case no attempt was made to close the vesical wound, and the supra-pubic wound was left to granulate, while the bladder was drained by a pair of drainage-tubes passing through the supra-pubic wound to the base of the bladder and outward over the pubes and down between the thighs, after the method of Perrier. The progress of the case was as satisfactory as could be expected; granulation took place and the wound ultimately healed, the patient being discharged cured at the end of the third or fourth week.

He thought the case presented had a bearing more particularly upon what seemed to be taking place at the present time—namely, a readjustment of views with regard to the relative merits of cutting and crushing methods for the removal of stones from the bladder.

Dr. Briddon asked Dr. Pilcher whether he objected to the operation of crushing.

Dr. Pilcher replied that he should not object to crushing, yet it seemed to him that under ordinary circumstances such an operation as this was more favorable for the patient. He might say, however, that he had been especially led to do the supra-pubic operation in this case to illustrate to the general practitioners who formed his class what he considered to be the best operation which would be available to those who had not acquired the technical skill necessary to crush a stone in the bladder.

Dr. H. B. Sands thought that it would hardly be proper to allow a case of this sort, successful as it was, to go without an expression of doubt as to the expediency, if not as to the propriety, of removing a stone of the size of the one presented, and which seemed to be friable, by any cutting operation. This patient had certainly recovered very promptly, else he would not have been shown within a fortnight; but it was probably within the experience of most of the surgeons present that, after crushing stones quite as large as this one, and even larger, the patients had been able to leave the hospital in the course of a week. He acknowledged the very great superiority of Petersen's operation in certain cases, but he thought it could not be recommended to the general practitioner as one free from risk. It seemed to him that it was one which would always require considerable skill in order to avoid danger to life, and our experience was not large enough to enable us to recommend it as preferable to one which had stood the test of extensive trial, and had proved to be almost absolutely safe in healthy young adults. As an example of successful operation he would accept Dr. Pilcher's case, but as an example for imitation he would reject it.

Dr. A. C. Post recalled a case in which he performed lithotripsy long before evacuation of the bladder had been introduced, three crushing operations having been performed at his clinic, the patient returning to his home on each occasion, a distance of about nineteen miles. No unpleasant symptoms developed.

Dr. Briddon said that within a few weeks past he had removed a stone by the crushing operation in a man over seventy years of age who had enlargement of the prostate and cystitis of an aggravated character. The operation lasted three hours, and more than six hundred grains of calculous material were removed, yet the man was able to leave the hospital within a week. Eight or nine days ago he performed Bigelow's operation on a man sixty-nine years of age, who left the hospital within a week with relief from his bladder symptoms. But he

thought there was sufficient justification for the operation performed by Dr. Pilcher, for he certainly would prefer to be cut for a stone than to have the stone crushed by a man who was not accustomed to do the crushing operation.

The PRESIDENT asked Dr. Briddon whether he would not consider the first case to which he had referred as specially suited for the high operation.

Dr. BRIDDON replied that he would not want any better result than that obtained by crushing.

The PRESIDENT said that would apply to Dr. Pilcher's case as well, which was altogether of a different character.

Dr. BRIDDON said that if he had cut this man he would have chosen the high operation in preference to the lower one. In such a case the high operation was certainly preferable.

Dr. POST asked if there were not two sides to that question. In case of enlarged prostate with cystitis, did not the low operation afford a fair prospect of relief of the prostatic and vesical difficulty independently of removal of the stone? A number of cases had been placed on record with such a result by high authorities, such as Sir William Fergusson, Mr. Reginald Harrison, Dr. Gouley, and others.

Dr. BRIDDON said that such had not been his experience. If relief followed the operation, it was only of short duration, the symptoms returning with as much severity as before.

Dr. T. M. MARKOE remarked that, after all, there remained a certain number of cases, small to be sure, in which Bigelow's operation was unsuitable by reason of the largeness or hardness of the stone, in which he thought the question as to the advisability of the high operation in preference to the low one fairly presented itself. As to a comparison of the high or low operation with crushing, general surgical experience was decidedly in favor of the crushing operation. But, in cases in which crushing was inadvisable, the high operation as modified by Petersen he regarded as, in certain cases, preferable to any other, and it must be accepted as an admirable contribution to modern surgery.

On Rupture of the Ligamentum Patellæ, and its Treatment by Operation.—Dr. SANDS then read the following paper:

Three forms of injury to the knee are closely allied, by their causes, effects, and principles of treatment. These injuries are: simple transverse fracture of the patella, subcutaneous rupture of the tendon of the quadriceps extensor muscle above that bone, and a corresponding lesion of the inferior division of the tendon, known as the ligamentum patellæ. The experience I have gained in the management of two cases of the last-named accident which have fallen under my observation has led me to a brief study of its literature, from which I have gleaned a few facts of sufficient interest, perhaps, to justify me in bringing the matter to the notice of the society. At the same time, I desire to put on record a number of cases of this injury hitherto unpublished, and to describe an operation for uniting the ends of the divided ligament by suture, which I have performed upon the patient now exhibited before you.

Compared with fracture of the patella, rupture of the ligamentum patellæ is a rare event. Maydl,* whose statistics are the largest I have yet met with, was able to collect only sixty-five examples of the latter form of injury. In this paper I am able to report thirteen other cases treated in the Bellevue, New York, St. Luke's, and Roosevelt Hospitals. In order to form a rough estimate of the comparative frequency of the two forms of injury, I have caused a search to be made of the entire records of the four hospitals above mentioned, and have obtained the following result:

	Fracture of patella.	Rupture of ligamentum patellæ.
	Cases.	Cases.
New York Hospital	150	3
Bellevue Hospital	140	7
Roosevelt Hospital	44	2
St. Luke's	19	1
Total	353	13

A comparison of these figures gives a ratio of about 25 to 1.

The relative infrequency of rupture of the patellar tendon may be ascribed chiefly to its greater strength and thickness, its being less exposed to direct injury, and the great mechanical advantage with which indirect violence often acts in causing fracture of the patella. Thus, as has been remarked, when the knee is bent, and a sudden and powerful contraction takes place of the quadriceps extensor muscle, as in endeavoring to prevent the body from falling backward, the patella is acted upon by two forces, which, as its upper and lower borders are then free from contact with the femur, may cause it to break, in the same manner as a stick may be broken by bending it across the knee.

The remarks I wish to make may conveniently take the form of a commentary upon the cases which have come under my care, or which, as will be seen in the appended table, have been gathered from the hospital records above mentioned. I shall give only my own cases in detail.

CASE I.—Patrick Fitzpatrick, a car driver, thirty-five years of age, was admitted to my department of the Roosevelt Hospital October 19, 1882. Ten years previously his right patella had been fractured by striking his knee against the pole of a truck. Five months later the same accident recurred, the final result being a fibrous union between the fragments, which remained separated a distance of two inches. On the day of his admission into the hospital, while in the act of hitching his horses to a street car, he missed his footing in attempting to ascend the platform, and felt something suddenly give way. An examination detected evidence of an old fracture of the right patella, which had been broken about its middle. The distance between the fragments measured two inches, and the interval was occupied by a broad, thick, fibrous band. In the normal situation of the ligamentum patellæ was found a shallow depression, dependent upon a complete rupture of the ligament, which seemed to have been torn close to its inferior extremity. The patient was entirely unable to extend the leg. Much tenderness and swelling of the knee were present.

Treatment.—Extension of the limb in the horizontal position, with an ice-bag applied to the knee.

October 28th.—Pain and swelling have subsided; vertical suspension of injured limb; rubber bandage to the knee.

November 14th.—Apparatus removed; limb kept extended, and raised on a pillow. The gap below the patella has filled up.

December 3d.—Water-glass bandage applied from ankle to thigh. Patient allowed to walk.

7th.—Discharged from hospital, wearing the splint.

November 21, 1885.—Patient re-examined, three years after the injury. He states that, disobeying the instructions he had received on quitting the hospital, he removed the splint a few days afterward, and began to use the limb more freely. His knee remained stiff, however, until five weeks later, when, in descending a staircase, and being within two steps of the bottom, he imagined he had reached the end, and, putting forward his left foot, a strain came on his right knee, which was suddenly and forcibly bent. Some pain followed, and he thought he was severely hurt; but the next day he discovered that he was better, and that he could readily flex and extend the leg. At present, as he is now exhibited before you, he can flex it a little beyond a right angle, and can make complete extension with some force. He says he is not aware of any difference in the strength of the opposite limbs. Separation of the patellar fragments, two inches; length of the ligamentum patellæ the same on both sides.

* "Zeitschrift für Chirurgie," vols. xvii and xviii, 1882 and 1883.

Evidently, in this case, the rupture of the ligamentum patellæ was due to the severe strain to which it had been subjected by the weight of the body and the forcible contraction of the quadriceps extensor muscle. Whether transverse fracture of the patella usually results from direct or indirect violence is an open question. I agree with those, however, who contend that this injury may generally be traced to the latter cause; and I am sure that the same is true regarding rupture of the ligamentum patellæ. Maydl, in investigating the ætiology of this accident, analyzed forty-four cases, in only five of which the rupture could be attributed to direct violence. Most often it is occasioned by a powerful contraction of the quadriceps, occurring in an attempt to save the body from falling backward; at other times from falling forward or sidewise. Violent flexion of the leg, accompanying a fall from a height, may produce it, and it has been known to occur spontaneously during an attack of convulsions, as also during forced flexion practiced with the object of overcoming an ankylosis of the knee. In the last case muscular contraction can not be concerned in the rupture, which must be ascribed in part to pathological changes in or around the affected joint. Adhesion and fixation of the patella, or rigidity and contracture of the quadriceps muscle, may, by preventing the descent of the patella when the knee is bent, cause the ligamentum patellæ to be lacerated during forcible flexion, either manual or instrumental.

In some of the cases I have collected from our hospital records the agency of muscular contraction in causing the rupture is plainly evident. The case just narrated (10) is one in point. In another case (4) the man, while wrestling, was thrown down, striking the left knee. As he fell, he was conscious that something had given way; and, on trying to get up, he found himself unable to extend the right, or opposite leg. Another man (7) stumbled while carrying a barrel of flour, and, in a violent but unsuccessful effort to save himself from falling forward, heard something snap, and felt his knee suddenly give way, as he came down with his left leg helpless. Another (6), whose heel had been caught between two flag-stones, and who squatted quickly to pick up his hat, felt something give way, and immediately fell to the ground, unable to extend his legs. In this case the rupture occurred on both sides. In Case 13 the man slipped while crossing the street, and did not strike the knee. In Case 12, to be related presently, the injury was certainly due to direct violence, a heavy piece of timber having fallen across the knee. One patient (9) fell from a roof, sustaining fracture of the left thigh and rupture of the left ligamentum patellæ. Here the violence may have been direct, as also in Case 2, in which a sailor fell from a jib-boom a distance of thirty feet, striking his knee; and in Case 11, in which a fireman was buried beneath a falling building, and, on being extricated, was found to have received a fracture of the femur, a rupture of the ligamentum patellæ, and severe contusion of the injured limb. In Case 1 the patient fell from a wharf into the water, striking his knee against a boat. Whether, in the four cases last described, the rupture of the ligament was caused by direct injury, by extreme flexion of the knee, or by muscular contraction, must be a matter of doubt, and in the remaining examples the doubt concerning this point must be still greater. Thus, one man (5), while engaged in carrying a plank, fell upon his left knee; another, who was assaulted by three men and knocked down in front of his lodging-house, struck his knee against the door-step. In Case 3 the patient, while walking, stumbled and fell, striking his knee against the ground. Now, in all these cases, the circumstance that the knee was hit seems to favor the supposition that the rupture was occasioned by direct violence. But it is quite likely that such an inference would be wrong, and that the fall upon the knee may have been the result, not the cause, of the rupture. This explanation is corroborated by the probability that, in all these instances, the extensor muscles were forcibly contracted at the moment the accident happened.

It is well known that rupture of the ligamentum patellæ is far more frequent in the male than in the female sex. I have been unable to find more than five published cases in which females have sustained this injury, and the thirteen subjects whose cases I have recorded were all males. The relative frequency of the accident in the latter may be accounted for by their greater exposure to its exciting causes, and by the greater strength and activity of their muscles.

In one case (6), already mentioned, the rupture took place on both sides simultaneously. Four other cases of this double injury have been recorded—namely, two by Shaw,* one by Gibson,† and one by Hamilton.‡ In three cases (3, 7, 10) the rupture occurred in persons who had previously suffered from transverse fracture of the patella on the same side. In Case 3 the patella had been broken one year previously, and ligamentous union had taken place. In Case 7 the fracture occurred eight months before the rupture, and the uniting band measured two inches in length. In Case 10 the fibrous band was likewise two inches long, while a period of ten years intervened between the fracture and the rupture. I have found elsewhere only four other examples of this singular sequence,# from which, I think, two conclusions may be drawn. The first is, that a fracture of the patella may establish a predisposition to rupture of the ligamentum patellæ. In Flower's case, in which the rupture took place at the patellar attachment, this end of the ligament seemed to have ossified during the repair of the fracture; and to this circumstance he was inclined to ascribe the predisposition. Such could not have been the explanation, however, in Markoe's case (3), nor in the one I have reported (10), as in both of these there was no evidence of ossification of the ligament, which, however, was found to be ruptured at its tibial insertion. In the majority of instances, probably, the essential cause of the predisposition is a weakness of the limb induced by the earlier injury, which renders the individual less able to avoid the accidents that determine the later one. The second inference is, that the fibrous bond of union between the fragments of a broken patella may be able to bear a greater strain than the normal patellar ligament. This may be the fact, even when the uniting band is of considerable length, as in the two cases I have recorded. Additional evidence of the occasional strength of the ligamentous union of patellar fragments is afforded by the numerous examples of refracture of the patella in which the second fracture has taken place through a part of the bone before uninjured. It is noteworthy that, when rupture of the ligamentum patellæ has been preceded by fracture of the patella, the two lesions have always been found to exist on the same side of the body. The longest recorded interval between the two accidents is ten years, in Case 10; the shortest, eleven weeks, in Flower's case.

In seven of the cases I have reported, the seat of rupture is definitely stated. In three it took place at the upper, and in four at or near the lower attachment of the ligament. In two cases a small fragment of the patella was torn off; in one of these it could be distinctly felt, and in the other it gave rise to

occasional crepitus when the ruptured parts were approximated. These results are in accordance with the general rule that the ligament is far less liable to give way in its middle than at one of its extremities, the lower being involved in about 50 per cent. of all cases. The rupture, wherever it occurs, is usually complete; my notes of thirteen cases furnish only a single instance in which a portion of the ligament remained intact.

The symptoms were in every case so plain as to leave no doubt concerning the nature of the injury. In one, the amount of retraction of the patella is said to have been slight; in another, it was two inches; and in all the gap between the severed parts could be distinctly made out. Prominent among the symptoms is inability to extend the leg. So far as I know, this loss of power is absolute when, as is usual, the rupture is complete. In transverse fracture of the patella, on the other hand, it occasionally happens that some power of extension remains immediately after the accident. An illustration of the preservation of this function to a remarkable degree came to my notice a few weeks ago, when a gentleman entered my office to consult me about an injury to his knee, which he thought he had sprained a few hours previously while playing in a tennis-court. In the mean time he had been able to walk, had gone down town to the Stock Exchange, and returned in a street car without suspecting the gravity of his injury, which, to my surprise, I found, on examination, to be a transverse fracture of the patella. The fragments, however, were in contact, and bony crepitus was well marked. We can readily understand why no such exception should ever be met with when the ligamentum patellæ is completely ruptured, since, under these circumstances, nothing is left to transmit the force exerted by the quadriceps except the insignificant aponeurotic attachment of a few of its fibers to the tibia.

The condition of the knee joint was noted in six cases, and in all but one the joint is said to have been distended and painful soon after the accident. Whether, as seems probable in this form of injury, the laceration extends into the joint, and whether the distension of the latter is due to the presence of blood or of inflammatory effusion, are points which have not yet been demonstrated. In any case, the swelling generally subsides, under appropriate treatment, in the course of a week or ten days.

The treatment adopted in most of the cases herewith reported was essentially the same as that usually followed in fracture of the patella, comprising extension of the knee, elevation of the injured limb, cold applications to the joint, and the use of pads, straps, and bandages for the purpose of approximating the ends of the ruptured ligament. As in the case of fracture of the patella, the retraction of the upper end appears to be largely owing to distension of the knee joint with fluid; and, until this has been absorbed or otherwise got rid of, any attempt to force it downward will prove futile, perhaps injurious. In one case (3), in which compresses and light bandages were employed very early, they certainly caused an aggravation of the symptoms, which compelled their removal, and a suspension of this part of the treatment for a period of four weeks. The final result, however, was satisfactory.

As a rule, such treatment as that described is followed by a fair amount of recovery of the functions of the injured limb. I regret that the notes of some of the cases I have collected are so defective regarding the results obtained as to possess little or no value. We know, nevertheless, that the continuity of the ruptured parts is usually restored in the course of six or eight weeks, the knee meanwhile gradually regaining its normal size and shape. Afterward the joint generally becomes movable, and the power of extension returns to a variable degree. Occasionally both the physical and functional results are excellent, as in Weir's case (13), in which, sixteen years after the injury, no difference could be discovered by measurement between the length of the patellar ligaments of the opposite sides, and in which the patient declared that the limb injured was quite as good as its fellow. Such a result, however, is exceptional, and the patella is apt to remain permanently more or less retracted, sometimes to the extent of several inches. Generally, as after fracture of the patella, the impairment of the power of extension bears a direct ratio to the length of the fibrous cord by which the severed parts are united; but this rule is not without exceptions. A case has been recorded in which a lengthening of six centimetres did not prevent complete voluntary extension of the leg; on the other hand, the power of extension may be seriously impaired, even when the uniting medium is short and firm. Here the disability is doubtless owing to some complication or sequel of the rupture, such as chronic inflammation of the knee joint, atrophy of the quadriceps muscle, or adhesions between the opposite surfaces of the upper part of the synovial sac which lies underneath the quadriceps. In such cases, flexion, as well as extension, is usually limited.

It is impossible to determine in what proportion of cases the power of extension is greatly damaged; but the number is larger than one would infer from a perusal of the published reports, in which very inferior results are often put down simply as "cures." We may be sure, however, that, in a certain number of instances in which no union takes place between the ruptured parts, the power of extending the leg will be entirely abolished, and the act of walking rendered impossible without assistance. Hitherto such cases have been treated by some form of mechanical apparatus designed either to prevent the knee from being bent, or to make artificial extension by means of an elastic force; but, so far as I am aware, no attempt has been made to re-establish the function of extension by an operation intended to restore the continuity of the ruptured ligament. Maydl states that, in a posthumous work by Veslingius ("Obs. anat. et posthum."), published in 1740, he found a notice of a case in which tenorrhaphy of the ligamentum patellæ was performed with success. He does not say, however, whether the injury was old or recent, and I have been unable to procure a copy of the work to which he alludes. In the case of the patient now exhibited I operated eight months after the accident, by bringing together the separated ends of the ruptured ligament and uniting them by sutures. The history reads as follows:

Case II.—Charles Kaulbach, a healthy man, forty-four years old, by occupation a rigger, was admitted, under my care, into the Roosevelt Hospital seven months ago, and gave the following history: In September, 1884, a heavy piece of timber fell across his right knee. He was at once disabled, and could neither walk nor extend the leg on the injured side. The accident occurred at sea, and the patient received no treatment beyond confinement in bed on account of pain and swelling of the knee. In December he entered a hospital in Calcutta, where the joint was incised to allow the escape of fluid. He recovered from the operation, but remained as weak as before in the knee, being unable to walk except when he wore a splint applied to the back of the limb in order to keep it straight. When he came under my charge he was still wearing a leather splint, which, although apparently well suited to its purpose, did not render locomotion easy. The gait was slow and unsteady, and the patient, otherwise in good health, was greatly discouraged in consequence of his infirmity, and declared his willingness to undergo any operation in the hope of regaining the usefulness of his limb. On examination, the right knee was found to be tender on pressure, and moderately swollen from an accumulation of fluid in the joint. The patella was displaced upward about two inches; it was freely movable laterally, but could not be drawn down to its normal position. Above, its relations with the quadriceps could be readily distinguished, but below it evidently had no connection with the tibia.

As nearly as I was able to ascertain, the ligamentum patellæ had

been completely ruptured close to its inferior point of attachment, and no attempt had been made to repair the injury. In place of the ligament there was a gap into which the skin could be readily depressed until the fingers encountered the femoral condyles. The power of extending the leg was entirely absent, and the patient, when lying upon his back with his leg extended, was unable to raise his foot from the bed.

On May 19th last I commenced an operation by making a longitudinal incision, six inches in length, in the median line on the anterior aspect of the knee, the center of the incision being opposite the lower edge of the patella. The cut was subsequently lengthened, both upward and downward, until it measured nine inches. On exposing the injured parts, in doing which the knee joint was freely opened, it was found that the ligamentum patellæ had been torn away from the spine of the tibia, which was now covered by only a small amount of dense fibrous tissue—sufficient, nevertheless, to allow a firm hold for sutures. A little more than an inch of the ligament, in good condition, was normally attached to the patella. There was a complete lack of union between the ends of the severed ligament, and a great deal of difficulty was experienced in bringing them together after they had been freshened with the knife. Before the upper end could be drawn down and placed in contact with the lower one, it became necessary to make many deep oblique and transverse incisions into the median and lateral portions of the quadriceps, and, even when this had been done as far as was deemed prudent, considerable force was required to secure apposition, which was maintained by two sutures of stout silver wire, the ends of which were twisted, cut short, bent flatwise, and buried in the wound. The mucous and alar ligaments were found redundant, and were partly removed with the curved scissors. The incisions in the capsule of the joint were closed by catgut sutures, and the external wound was united, except at its upper and lower ends, in the same manner. Two bone drains, one on each side, were inserted into the joint through openings made for that purpose, and one into each extremity of the median incision. During the operation a solution of mercuric bichloride, 1–1,000, was applied freely to the wound, which was afterward covered with iodoform gauze. The limb was next enveloped in a moss-bag, moistened with the bichloride solution, and finally fastened to a long, straight wooden splint, provided with a foot-piece. Previous to the operation the knee and adjacent parts had been shaved, scrubbed several times with soap and water, then washed with oil of turpentine, and finally disinfected with a solution of mercuric bichloride.

The subsequent progress of the case was uneventful, except that, during the first four days, the patient complained of almost constant pain. This was so severe on the second day that I removed the dressing and examined the wound, which, however, showed nothing which would account for the man's suffering. The drainage-tubes were cleared of a few clots of blood, and a fresh dressing like the first was applied. On the fourth day the pain began to diminish, and soon afterward it disappeared altogether. The wound was not dressed again until July 7th, seven weeks after the operation. It was then discovered that the wound had long before healed by primary union, except at its lower angle, where a minute skin ulcer remained, marking the site of one of the drainage-tubes. The wounds made for draining the joint were entirely closed. The patella was movable, as was also the knee joint, but no attempt was made to bend the leg beyond a few degrees. On July 21st the patient was allowed to get up, wearing a water-glass bandage. This could not be worn with comfort, and, a week later, was replaced by a leather splint, with which the patient walked about without much difficulty. He continued to use the splint until October, when he laid it aside. Meanwhile the knee has assumed nearly its natural size and shape, and it is evident that continuity of the ruptured parts has been re-established.

My house surgeon, Dr. George S. Huntington, has, at my request, furnished me with the following precise description of the patient's present condition, which can be verified by the members of the society:

"Measurements.—*Thigh:* Circumference at upper border of patella.—Right thigh, 13¾″; left thigh, 14″. Circumference at junction of middle and lower thirds.—Right thigh, 13½″; left thigh, 15½″. *Knee:* Circumference of knee joint over the patella.—On both sides, 13·9″. *Leg:* Circumference at junction of upper and middle thirds.—Right leg, 12¾″; left leg, 13″. Distance from tip of internal malleolus to lower border of patella.—Right side, 15·6″; left side, 14·4″.

"Functional Result.—A line drawn from the middle of the upper border of the great trochanter to the center of the outer surface of the external condyle is taken as the axis of the thigh. The axis of the leg is represented by a line drawn from the tip of the external malleolus to a point just anterior to the superior tibio-fibular articulation. On the left side, in full extension of the leg, these lines form with each other an obtuse angle of 174°. On the right side, when the patient is in the recumbent position, the amount of voluntary extension is as follows, the axis of thigh and leg forming an obtuse angle of 148°. When the patient is in a sitting posture the amount of extension is increased to 155°. *Passive Motion:* Extension of the leg possible to the normal limit; flexion to a right angle; rotation of the leg the same on both sides."

I will add that, in walking, the patient can easily and completely extend the leg; that for several weeks past he has been able to go up and down stairs without assistance; and that his limb is so steadily gaining in strength and freedom of motion as to warrant the hope of further improvement.

At all events, I think it will be admitted that, in this case, the operation has conferred a great benefit upon him by restoring the usefulness of the limb; and that, in similar cases, suturing of the ligament deserves a further trial. The principal difficulty likely to be encountered when the injury is not of recent date is that of bringing into contact the ends of the ruptured ligament. In my case this was accomplished only after the rectus and the vasti muscles had been extensively scored; and even then the parts could not be brought together without decided tension. I am inclined to believe that the pain the patient complained of during the first four days after the operation was caused by the traction of the sutures, and that it was relieved only when the sutures had cut through and receded far enough to moderate the existing tension. And, although I neglected to note the level of the patella immediately after the operation, its present elevation may be held as proving that the segments of the ruptured ligament separated from each other to a considerable extent after they had been sutured, the gap so formed being now occupied by newly formed ligamentous tissue, like that which, in ordinary cases of this injury, is furnished to repair it.

That which has most interested and gratified me in this and in several other severe operations I have performed in which the knee joint has been involved, is the impunity with which this articulation may be opened, and indeed somewhat roughly handled, provided antiseptic precautions are scrupulously observed. This fact was especially forced upon my attention in a case of old fracture of the patella in which I wired the fragments one year ago in the Roosevelt Hospital. The operation was performed in the usual manner, but the fracture was found to have been comminuted, and the fragments could not be brought into apposition without much difficulty, nor until the quadriceps muscle had been extensively exposed and repeatedly cut in order to obtain the necessary elongation. Meanwhile the bleeding was free, the knee joint was frequently sponged out and irrigated, and the operation was prolonged as well as severe. Yet the patient recovered, without an unpleasant symptom, under the use of a single dressing; and, when this was removed at the end of eight weeks, I discovered that the wound had healed throughout by the first intention, and that neither suppuration nor adhesive inflammation had taken place within the joint, which had a limited range of easy motion. Such cases afford, according to my judgment, indubitable proof of the marvelous improvements in operative surgery which have been wrought by antiseptic methods; and, when I see it stated in a standard American text-book, published only three months ago, that "the alleged superiority of the antiseptic method can not be

said to have been as yet demonstrated," I am amazed at the author's incredulity. Even among those who practice antiseptic surgery, however, some hesitation is occasionally felt about opening the larger joints; and operations involving the healthy knee joint are at present regarded by many with the same kind of apprehension which, not a great many years ago, deterred surgeons from invading the peritoneal sac. The latter procedure is, as we now know, reasonably safe; and I can not doubt that the operation of opening the knee joint is already, when properly performed, far safer. I confidently anticipate the time when skillful and careful surgeons will be able to divest it of all danger, either to life or to limb; and, whenever this period arrives, our time-honored but clumsy, tedious, and uncertain methods of treating both fracture of the patella and rupture of its ligamentous attachments may well be abandoned in favor of some form of operation calculated to secure an immediate union of the divided parts.

Dr. R. F. Weir exhibited the patient treated in St. Luke's Hospital for rupture of the ligamentum patellæ, who was referred to in Dr. Sands's paper. The accident occurred in 1869. The patient, a man aged forty-seven, while crossing the street, slipped and fell, but did not strike the knee. The rupture resulted apparently from his attempts to save himself from falling. He was taken immediately to the hospital. The patient was recently looked up, and, when asked, in the absence of a written history, upon which side the accident occurred, said the left; but he had since thought over the matter a good deal and was unable to say positively whether the right or the left leg was affected. The result was a remarkably good one, both as to function and as to physical appearances. The patient could

Case.	Hospital.	Age and Sex.	Date	Observer.	Side of rupture.	Cause.	Condition.	Treatment.	Results.
1	New York.	32; Male.	1844.	....	Right	Fall from a wharf into water, striking knee against a boat.	Joint much swollen; rupture at patellar insertion, carrying away a minute fragment of bone; patella not much retracted, and easily brought down.	Leeches, poultices, low diet; at end of ten days, pads and straps.	Firm union. Discharged "cured" at end of four months.
2	New York.	26; Male.	1854.	Watson	Right	Fall, thirty feet, striking knee.	Rupture of ligament just above tibial insertion; joint distended and painful.	Extension, cold lotions; crutches after four weeks.	Discharged "cured" at end of two months.
3	New York.	32; Male.	1859.	Markoe.	Left.	Slipped and fell, striking left knee.	Marks of fracture of patella sustained a year previously; fragments united by ligament; patellar ligament ruptured at tibial insertion; joint greatly distended and painful.	Single inclined plane, evaporating lotions, compress and bandage, which had to be removed on account of pain; reapplied four weeks later.	Discharged eleven weeks after accident, with firm union.
4	Bellevue.	60; Male.	1870.	Hamilton.	Right	While wrestling was thrown on left knee, and felt something give way. On attempting to get up he was unable to extend right leg.	Ruptured ligamentum patellæ.	Plaster-of-Paris bandage; figure-of-eight bandage to knee.	
5	Bellevue.	40; Male.	1874.	....	Left.	While carrying a plank, patient fell, striking left knee.	Complete rupture of ligament. Patient unable to stand or to extend leg; no pain or distension of joint.	Plaster-of-Paris bandage day after accident; renewed three times, and finally removed at end of six weeks.	Ligament united to tibia; knee somewhat stiff when patient was discharged eight weeks after injury.
6	Bellevue.	50; Male.	1874.	Wood.	Both.	Patient, whose heel had been caught between two flagstones, squatted quickly to pick up his hat, felt something give way, and fell to the ground helpless.	Each patella retracted from rupture of ligament; any extension of legs absolutely impossible.	Commenced seven months after injury. Posterior splint, figure-of-eight bandage.	Left hospital a fortnight after admission. Result not known.
7	Bellevue.	22; Male.	1874.	....	Left.	Patient, while carrying a barrel of flour, stumbled, and made a powerful effort to save himself from falling forward; heard something snap as he fell; found left leg helpless.	Signs of old fractured patella (eight months previously); firm fibrous union, 2 inches in length; immediately below the patella a groove corresponding with the ruptured ligament.	Posterior splint.	
8	Bellevue.	52; Male.	1878.	Stephen Smith.	Left.	Was knocked down, striking knee against door-step.	Much swelling and effusion in joint; rupture of ligament close to its attachment to patella.	Posterior splint, ice-bag; afterward figure-of-eight bandage, and traction with adhesive plaster.	Patient discharged with stiff knee eight weeks after injury.
9	Bellevue.	10; Male.	....	....	Right	Fall from a roof.	Fracture of left femur; rupture of right ligamentum patellæ incomplete, a few fibers only remaining intact.		
10	Roosevelt.	35; Male.	1882.	Sands.	Right	Slipped while getting on a street-car, and felt something give way.	Marks of old fracture of patella; fibrous uniting band two inches long; ligamentum patellæ ruptured near its tibial insertion.	Ice-bag; extension, at first horizontal, afterward vertical; rubber bandage.	Recovery, with useful limb.
11	Bellevue.	34; Male.	1884.	Dennis and Bryant.	Left.	Buried beneath a falling building.	Rupture of ligamentum patellæ; fracture of lower third of femur; severe contusion of limb.	Double-inclined plane for thirteen days; Buck's extension, twenty-five days; plaster-of-Paris bandage, six weeks.	Two years after injury patient has a stiff knee, with the leg extended; flexion easy to the extent of 5–10 degrees, where it is suddenly checked, apparently in consequence of adhesion and condensation of the quadriceps at the seat of fracture. Ligamentum patellæ reunited and firm, being lengthened only half an inch; patella movable laterally, but not downward; contraction of quadriceps causes no tension of ligamentum patellæ.
12	Roosevelt.	44; Male.	1885.	Sands.	Right	Blow from a heavy piece of timber.	Eight months after accident, power of extension entirely lost; patella retracted two inches; a depression in place of ligamentum patellæ, which seems to have been ruptured near tibial attachment.	Joint opened; ligament sutured.	Six months after operation, power of extension regained sufficiently to enable patient to walk with ease.
13	St. Luke's.	47; Male.	1869.	Weir.	Left.	Slipped while crossing street; did not strike his knee; walked, with assistance, twenty or thirty feet after the accident.	Rupture of patellar ligament.	Limb extended in plaster-of-Paris splint for six weeks.	Began to walk soon after removal of splint. Sixteen years later (1885), injured limb as good as other. Ligament same width and length as other by measurement.

use one limb as well as the other. Dr. Weir was unable to detect any difference in the appearance or length of the two patellar ligaments. The man was treated in the hospital about a month with a plaster-of-Paris splint. He then went home, and, by incautious walking, got up a synovitis and was confined to his house for another month.

Dr. Weir said four cases of rupture of the ligamentum patellæ had come under his notice, the first being during his interne service in the New York Hospital, and probably the one reported by Dr. Sands as occurring in that hospital under the care of Dr. Markoe. The second was the one narrated to-night. The third occurred in a gentleman from the West, treated at the Sturtevant House. The result was uncertain as to function, as he was treated only three or four weeks, when he went to his home, but union had taken place satisfactorily. The fourth case, which, however, did not properly belong to the class referred to by Dr. Sands, occurred in a case of stiffness of the knee joint supposed to be due to fibrous ankylosis of the patella, and in which an attempt was made to practice *brisement forcé*, with the result, not of fracturing the patella, but of rupturing the ligamentum patellæ. It healed promptly. Dr. Weir further reported that within the past two weeks he had been consulted by Dr. Loring, of Valparaiso, Ind., about the case of a woman, sixty-five years of age, who fell and sustained a rupture of the ligamentum patellæ on the left side from muscular violence. The gap was now of the breadth of a hand, and the limb was incapacitated except with the use of a posterior splint which enabled her to get about by the aid of crutches. The case was additionally interesting as having occurred in a female. Dr. Weir thought it was not generally enough recognized that the ligamentous band uniting the fragments of a fractured patella was frequently stronger than the bone itself.

Dr. Weir remarked that it had been suggested, as a means of overcoming the distance between the fragments of a recently fractured patella, to fracture the thigh bone; might this not be resorted to as a last measure in certain instances, where an operation was required, when the scoring of the quadriceps muscle would not permit the approximation of bony fragments in fracture of the patella, or of the tendon ends in rupture of the ligamentum patellæ?

Dr. L. A. Stimson said that the creation of a gap in cases of rupture of a tendon at its lower end was not produced solely by contraction of the muscle, as of the quadriceps femoris, but was produced in part, as in Dr. Sands's case, by retraction of the ligament itself. This had been observed constantly after fracture of the patella, and it was one of the reasons why it was so difficult to obtain union without a gap after that accident. Fracture of the thigh would not overcome a gap due to that cause.

The President would suggest the substitution of division of the patella for fracture of the thigh bone in certain cases for overcoming the gap, trusting to the well-known facility of formation of a ligamentous band to unite the divided patella. This procedure might be resorted to in some cases in which the separation was great and could not be overcome by division of the muscle.

Pott's Fracture at the Ankle.—Dr. Stimson presented a specimen illustrating a common fracture, but one in which we seldom had an opportunity to obtain the injured parts for study. The patient was sixty years of age, and sustained Pott's fracture at the ankle from a fall apparently caused by a cerebral lesion. He died three days after admission to the hospital. The characteristic deformity of the fracture was present, and crepitus was much more marked than usual. At the autopsy the fracture was found to be very oblique, beginning in front, an inch and a half above the tip of the malleolus, and extending upward and backward more than two inches. The internal lateral and lower tibio-fibular ligaments were ruptured, and the outer malleolus was displaced from a half to three quarters of an inch outward from the tibia. There was no fracture of any other part.

Miscellany.

The Mitral Cardiac Murmurs.—The study of the mitral cardiac murmurs at the present time is of importance to every medical practitioner, as well as of interest to those whose attention is especially directed to the diseases of the heart. In an able article in the January number of the "American Journal of the Medical Sciences," Dr. Austin Flint reviews our existing knowledge of these murmurs. He holds that there are four mitral murmurs—namely, (1) the systolic regurgitant, (2) the systolic non-regurgitant or intra-ventricular, (3) the presystolic, and (4) the diastolic. Each of these four murmurs has distinctive characters which individualize it. Two, three, and even all four may be combined in the same case. This statement, as will be seen, applies to the systolic regurgitant and to non-regurgitant murmurs. The names post-diastolic and post-systolic, proposed by Hayden, seem to the author unnecessary refinements, and, therefore, objectionable. If the reader would stop to reflect upon the inquiry whether the mitral murmurs offer topics for consideration and discussion of sufficient interest and importance to occupy the thirteen and one half pages which Dr. Flint devotes to them, let him refer to that portion of the elaborate and able work on diseases of the heart, by Hayden, which treats of the cardiac murmurs. He will there find a statement of the defects in our existing knowledge, together with differences of opinion in regard to the number of the mitral murmurs, their characters, their significance, and the modes of their production, which must convince him that they afford scope for an article extended much beyond the limits to which the author restricts himself. In fact, the object of the article is to present certain conclusions and suggestions without attempting to consider the subject comprehensively and fully.

On the Dilatation and Hypertrophy of the Heart which are not produced by Changes in the Valves.—That all the examples of cardiac hypertrophy and dilatation which we meet with in practice are not due to valvular lesions is a proposition which every one will admit. That attention has been called to such non-valvular cases by a number of authors is evident to any one who reads medical literature. And yet the recognition of these cases and their treatment have not become matters of ordinary practice. Dr. Francis Delafield (*Ibid.*) has been led, therefore, to group together the cases of cardiac dilatation and hypertrophy not due to valvular disease; to subdivide the group into its appropriate classes, and to state the characteristics of each class. Under the heading of dilatation of the ventricles occurring without discernible cause, Dr. Delafield gives sixteen clinical examples. Most of the patients were males, and many of them young adults. The invasion of the symptoms was sudden in seven cases, gradual in five, and in three was not stated. The disease ran in some cases an acute, in others a chronic course. In his own cases the shortest period was twenty-four days, the longest fifteen months. The heart's action was irregular and feeble, the physical signs of dilatation were evident; in some of the cases there was a systolic murmur, in others none. The dyspnœa was in most of the cases a marked symptom. Dropsy was developed in the more protracted cases, but not in those of shorter duration. The urine was diminished in quantity, the specific gravity being from 1·010 to 1·026; there was no albumin present, or but very little. The dilatation regularly involved both ventricles, and hypertrophy was the exception. The lungs, liver, stomach, spleen, and kidneys regularly presented the condition of chronic congestion which belongs to marked valvular lesions of the heart. The course of the disease was from bad to worse, and even the symptoms were but little alleviated by treatment.

The Theory of Bronchial Asthma, viewed in the Light of the Pathology of Hay Fever.—Hay fever occurs in winter or spring; some-

times it occurs at sea, or in the heart of a great city; sometimes, when no pollen can be found in the air, it arises after a full meal, or in the middle of the night; sometimes it appears almost instantaneously under the influence of intense light, the heat of a great fire, the odors emanating from certain localities, plants, and animals, some particular place or position occupied in driving, or from emotions and vivid ideas. In an able and suggestive paper (*Ibid.*) Sir Andrew Clark points out that in these and in all like cases there are clearly two main factors at work, a certain local or constitutional predisposition, and some immediately acting excitiug cause. That some such predisposition exists is plainly proved from the fact that the exciting agents which produce the malady in one class of persons entirely fail to produce it in another; and that these excitiug agents, in their relations to the persons acted upon by them, are in a remarkable manner specialized seems also proved by the circumstance that the emanations from a stable, which in one person provoke a severe attack, produce in another, liable to hay fever, no sensible effect. And of the persons subject to this disease, it must be said that they are not always affected in the same manner by the same agent; for sudden intcuse light which may bring on an attack at one time will quite fail at another; and so we are compelled to conclude that the organism, or some particular part of it, varies so much in its conditions that its relations to its euvironments are capable, without seusible structural alteration, of becoming completely changed. When we inquire into the family and personal history of an individual subject to hay fever we shall discover as the prominent point in it that the patient and his people are more or less "neurotic." There may be found among members of the patient's family the disease of which he is himself the subject, gout, such skin troubles as urticaria and eczema, migraine, neuralgia, epilepsy, and no inconsiderable sprinkling of pulmonary disease. But that which will be found the most widely, and will connect them all, will be a sensitive, an irritable, aud an unstable nervous system. In a scries of propositions the author sets forth what he regards as the teaching of a study of hay fever coucerning the pathology of bronchial asthma, holding that it is a neuro-vascular trophic disease, and has its roots in a special vulnerability of the respiratory mucous membrane, of the respiratory nerve-centers, and of certain portions of the sympathetic.

Notes toward the Formation of Clinical Groups of Tumors.—Mr. Jonathan Hutchinson, of London (*Ibid.*), says that, in his opinion, the time has arrived when it is both possible and desirable to make, for practical purposes, a much more detailed classification of tumors than has yet beeu attempted. Some grouping of the kind is needed, both for purposes of prognosis, and in order that we may lay down good rules for treatment. Such grouping must be accomplished chiefly by observation of external features of similarity, and of resemblance in general tendency. It is these conditions, rather than minute histological differences, which will be of chief assistance to the surgeon; or, perhaps, it may be convenient to have two classifications side by side, the one clinical the other histological, and let the two help each other at all points where mutual help is possible. Mr. Hutchinson does not attempt the ambitious task of presenting an arrangement of new growths based upon their clinical features and like histories. He is, however, so convinced, both of its desirability and of its practicability in the future, that he ventures to offer a few hints and detached memoranda, which may possibly prove helpful toward its attainment at some future time.

Treatment of Intestinal Obstruction by the Force-Pump.—Dr. H. Illoway, of Cincinnati (*Ibid.*), advocates the employment of enemata administered with sufficient penetrating power to pass beyond the ileo-cæcal valve and into the small intestines, and to produce peristaltic action. He advocates the use of the force-pump, and maintains (1) that enemata thus administered are superior to every other method of treatment in the rapidity with which they either relieve the symptoms or clearly indicate the necessity of surgical interference; (2) that they are entirely free from all danger, and in no way prejudice the ease should a surgical operation become necessary.

The Remains of William Harvey.—We desire to again call the attention of our readers to the effort being made for the restoration of Hempstead Church, where Harvey's remains were deposited, and to state that any subscriptions forwarded to us for that purpose will be duly acknowledged and forwarded to the treasurer of the Londou committee.

The New York Polyclinic.—Dr. Henry C. Coe has been appointed instructor in gynæcology, to fill the vacancy occasioned by the resignation of Dr. Clement Cleveland.

The Long Island College Hospital.—Professor A. P. Grinuell, M. D., of the faculty of the University of Vermont, will give the course of lectures on the practice of medicine at the Long Island College Hospital the coming year.

Brown vs. Purdy.—The facts of this case are briefly as follows: In November, 1879, Dr. A. E. M. Purdy was called to see Miss Angelina Brown. On his arrival he diagnosticated small-pox. He saw her later iu the day with Dr. A. S. Purdy, who likewise diagnosticated small-pox. Still later he saw her again with Sanitary Inspector Dr. C. E. Lockwood, whom he had uotified of the case. Dr. Lockwood's diagnosis was small-pox. The patient went or was sent to the small-pox hospital. On her arrival, the house physician, Dr. Bowen, made a diagnosis of small-pox, and so reported to the Board of Health. He subsequently revised his diagnosis and certified that Miss Brown was only suffering from eczema, and told her that she need not remain in the hospital. She voluntarily remained there, however, for some days.

After leaving the hospital she brought suit against the Drs. Purdy, claiming damages to the extent of $10,000. She asserted that the diagnosis made by Dr. A. E. M. Purdy, Dr. A. S. Purdy, and Dr. C. E. Lockwood was incorrect, that she had been damaged to the above-named amount by being sent to the small-pox hospital, and that she was sent there through the agency of the Drs. Purdy.

On the trial of the cause, in November, 1885, in the Superior Court before Judge Ingraham, the counsel for the defendants moved to dismiss the complaint, on the ground that the defendants had not sent the plaintiff to the small-pox hospital, but that the sending of Miss Brown to the hospital was the act of the Board of Health, for which the defendants were not responsible.

His Honor denied the motion, and ordered that the trial proceed before the jury.

The plaintiff on the stand gave a lengthy history of her experiences, and declared that she was not suffering from small-pox in November, 1879, but from the effects of a local irritant that she had applied to the skin.

The defendants testified minutely as to the symptoms and eruptive appearances present at the time of their examination, and declared that they were unmistakably indicative of small-pox.

Dr. Lockwood testified to the same effect, that his opinion was formed independently of the Drs. Purdy, and *that Miss Brown was sent to the hospital in conformity with the rules and regulations of the Board of Health.*

Dr. Austin Flint, Dr. E. L. Keyes, and Dr. George H. Fox testified that, from the recital of the symptoms and the character of the eruption, as detailed by witnesses, Miss Brown was undoubtedly suffering from small-pox at the time referred to. Other physicians were in court prepared to testify to the same effect.

At the close of the testimony the counsel for the defense again moved that the case be dismissed on substantially the same grounds as before, to wit: that it was the Board of Health, and not the Drs. Purdy, that caused the transfer of the plaintiff to the hospital.

His Honor again denied the motion, and in his charge to the jury said in effect that *the defendants had set in motion the machinery* that led to the plaintiff being sent to the hospital.

The jury brought in a verdict of $500 against the defendants.

The features of the case that are important to the medical profession of this State do not hinge on the correctness or otherwise of the diagnosis.

The essential point is whether a physician who complies with the law requiring him to report cases of suspected small-pox thereby becomes liable for any damage arising or claimed to have arisen through the subsequent acts of the Board of Health.

The decision of Judge Ingraham in sending the case to the jury would imply that the physician may thus become liable.

This decision, in accordance with judicial custom, will be considered law until reversed by a higher court.

The case of Brown *vs.* Purdy having been brought to the notice of the Medical Society of the County of New York, that body referred the matter to its *Comitia Minora*, with power. The Comitia, believing that it would be expedient to appeal from Judge Ingraham's decision, provided sufficient funds could be raised, appointed a special committee, consisting of members of the society, for the purpose of raising said funds.

This committee appointed a sub-committee to prepare a brief statement of the facts of the case, and the foregoing is their report.

[Signed] H. G. Piffard,
Daniel Lewis,
P. A. Morrow,
Frederick R. S. Drake,
A. H. Smith,
Sub-Committee.

In the light of the facts, as above stated, the special committee earnestly urge the members of the Medical Society of the County of New York to contribute to the fund now being raised for the purpose of carrying the case to the higher courts. To this fund Dr. A. E. M. Purdy has subscribed one thousand dollars, and Dr. C. R. Agnew five hundred dollars. Other subscriptions of one hundred dollars and under have been received. Additional funds are still needed, and may be sent by check or otherwise to the treasurer of the committee, Dr. A. B. Douglas, 123 East Thirty-sixth Street. Any part of the fund not required will be returned, *pro rata*, when the suit is decided.

By order of the Special Committee.

[Signed] Daniel Lewis, *Chairman.*
F. R. S. Drake, *Secretary.*

The Importance of Mechanical Training to Medical Men.—We are allowed to make the following extract from a letter lately written by Dr. Morris H. Henry, of New York, in answer to an invitation to be present at a meeting held in reference to the Gramercy Park School and Tool House: "I have always felt a sincere interest in the development of every industrial art, and the education and training of boys to manual labor. It is the basis of and incentive to progress and success. In the practice of my own profession, whether in chemistry, experimental physiology, or practical medicine or surgery, this want and absence of early manual training are severely felt when, alas! it is almost too late for their repair to be of good service. A good knowledge and training of the hands—guided by average intelligence—are not yet fully appreciated by a large proportion of those on whom we depend for skilled industrial work. I speak from personal experience. A portion of my early school-days was spent in a school of art. The inspirations and practical advantages of that atmosphere have been of no small benefit to me in the practice of medicine. The labor you have assumed must bear good fruit."

The Physiology of the Bile.—In an article on Ideal Cholecystotomy, etc., published in the "Weekly Medical Review," Dr. Augustus C. Bernays, of St. Louis, says:

"But little is known of the influence and uses of the human bile. We thoroughly understand its chemistry, we know approximately the quantity of the secretion. As good as nothing is known of the use and function of the gall-bladder. We do not know whether it is filled and emptied periodically, or whether the flow is a constant one. I have vainly searched in literature for a statement of the amount of pressure normally present in the bladder or the ducts. In a case where I performed laparotomy on the supposition of cholelithiasis I found the gall-bladder a flabby sac, containing no calculi, and I could squeeze the bile out of the bladder with great ease by compressing the thin normal sac. There was certainly no amount of pressure in this flabby sac. It is certain that the glands in the walls of the bladder secrete mucus. Lawson Tait believes this mucus contains some kind of ferment. The fibrous layer of the gall-bladder contains some muscular tissue. I have found it present in all bladders, but it is very thin and weak. Since the operation of cholecystotomy with the establishment of an abdominal direct biliary fistula has been performed on the human subject, numerous observations and experiments have been made in order to determine the use of the bile to the organism. In a number of cases where these fistulæ persisted for months (seven months in one case), the stools were almost milk-white and the entire amount of the bile dribbled out of the fistula, not the slightest symptoms of disease or disturbed digestion or alimentation could be observed. The administration of calomel, iron, salts, podophyllin, aloes, or rhubarb does not seem to have the slightest effect upon the quantity or chemical constituents of the secretion. No effects have been noticed either after the administration of quinine, morphine, or cocaine. In some cases the patients have gained in weight and health while losing all their bile through a fistula. Tait says there is not the slightest evidence of flatulence and decomposition which are said in the text-books to accompany biliary fistula. After a careful perusal of all the accessible literature on this subject I have come to the conclusion that the bile is almost, if not entirely, as much of an excretion as the urine. Even the much-praised emulsifying power of the bile is probably only an accidental quality, certainly not a necessary one. The trypsin of the pancreas, according to Kuehne, is entirely sufficient to emulsify all the fats that come into the intestines."

THERAPEUTICAL NOTES.

Tartar Emetic in the Treatment of Consumption.—Bucquoy ("Gaz. des hôp."; "Ctrlbl. f. klin. Med.") has been led by a number of successes to recommend this drug anew. At first he gives from a grain and a half to two grains and a quarter in the course of the day, restricting the drink, in order to prevent vomiting. The daily amount is then reduced to three quarters of a grain, and its use is continued, with the result of diminishing the fever, increasing the appetite, overcoming constipation, allaying the cough, and reducing the expectoration. The only contra-indication consists in diarrhœa and intestinal ulceration.

Cotton Root in the Treatment of Uterine Hæmorrhage.—Massini ("Korrespondenzbl. f. Schweiz. Aerzte;" "Ctrlbl. f. klin. Med.") thinks that this drug is to be regarded not only as an efficient substitute for ergot, but as having some advantages over that remedy. Although less prompt in its action, it is more enduring; hence, while it has been used successfully to increase the pains of labor and in uterine atony in the placental stage of labor, its most appropriate field is in gynæcological practice. In two cases of metrorrhagia at the menopause the author observed brilliant results from the use of the fluid extract, two or three teaspoonfuls daily.

Pichi, a Chilian Remedy for Cystitis.—Pichi is the name given in Chili to the *Fabiana imbricata*, a plant indigenous to that country, where it is in great repute in the treatment of urinary diseases, even those due to renal and vesical calculi. Dr. A. Rodiguez ("Diario Médico-farmaceutico"; "Med. Times and Gaz.") thinks it especially valuable in catarrh of the bladder from lithiasis, and in certain tropical affections of the liver. In Rio de Janeiro it has been found useful in several cases of jaundice, dropsy, and dyspepsia from deficient biliary secretion. It has been found to contain a highly aromatic essential oil, a resin, and a fluorescent substance resembling esculin, paviin, and fraxin, which crystallizes in needles.

Iodide of Mercury and Sodium.—Dr. L. Vacher ("Gaz. hebdom. de méd. et de chir.") recommends this double salt for hypodermic use in the treatment of syphilis, according to the following formula:

Biniodide of mercury, Iodide of sodium,	each	1 part;
Distilled water		10 parts.

Dissolve with the aid of heat, and add 190 or 90 parts of distilled water, accordingly as a one-half-per-cent. or a one-per-cent. solution is desired. The maximum dose of the latter is fifteen drops, but smaller ones should be used at first. If need be, the injections may be repeated several times in the course of a day.

Sphacelinic Acid in the Treatment of Rosacea.—At the Fifty-eighth Congress of German Naturalists and Physicians, Dr. Unna ("Dtsch. Med.-Ztg.") reported excellent results in the treatment of uncomplicated cases of rosacea with ointments containing from five to ten per cent. of an extract of ergot that was rich in sphacelinic acid (either that known to the trade as Gehe & Co.'s "extractum secalis cornuti cornutino-sphacelinicum" or an extract prepared by Mielck, of Hamburg).
